Serum 25-Hydroxyvitamin D Levels Among US Children Aged 1 to 11 Years: Do Children Need More Vitamin D?

WHAT’S KNOWN ON THIS SUBJECT: Single-center studies have suggested that hypovitaminosis D is widespread. Our objective was to determine the serum levels of 25(OH)D in a nationally representative sample of US children aged 1 to 11 years.

WHAT THIS STUDY ADDS: On the basis of a nationally representative sample of US children aged 1 to 11 years, millions of children may have suboptimal levels of 25(OH)D, especially non-Hispanic black and Mexican American children. It is likely that many US children need more vitamin D.

abstract

OBJECTIVE: Single-center studies have suggested that hypovitaminosis D is widespread. Our objective was to determine the serum levels of 25-hydroxyvitamin D (25(OH)D) in a nationally representative sample of US children aged 1 to 11 years.

METHODS: Data were obtained from the 2001–2004 National Health and Nutrition Examination Survey. Serum 25(OH)D levels were determined by radioimmunoassay and categorized as <25, <50, and <75 nmol/L. National estimates were obtained by using assigned patient visit weights and reported with 95% confidence intervals (CIs).

RESULTS: During the 2001–2004 time period, the mean serum 25(OH)D level for US children aged 1 to 11 years was 70 nmol/L (95% CI: 68–73). Children aged 6 to 11 years had lower mean levels of 25(OH)D (68 nmol/L [95% CI: 65–71]) compared with children aged 1 to 5 years (74 nmol/L [95% CI: 71–77]). Overall, the prevalence of levels at <25 nmol/L was 0.7% (95% CI: 0.4–1.3), <50 nmol/L was 15% (95% CI: 12–18), and <75 nmol/L was 65% (95% CI: 58–71). The prevalence of serum 25(OH)D levels of <75 nmol/L was higher among children aged 6 to 11 years (71%) compared with children aged 1 to 5 years (56%); girls (67%) compared with boys (62%); and non-Hispanic black (89%) and Mexican American (77%) children compared with non-Hispanic white children (54%).

CONCLUSIONS: On the basis of a nationally representative sample of US children aged 1 to 11 years, millions of children may have suboptimal levels of 25(OH)D, especially non-Hispanic black and Mexican American children. More data in children are needed not only to understand better the health implications of specific serum levels of 25(OH)D but also to determine the appropriate vitamin D supplement requirements for children. Pediatrics 2009;124:1404–1410

Vitamin D₃ (cholecalciferol) comes from 2 sources: exposure to UV-B rays in natural sunlight and dietary intake (including supplements). Because few foods contain vitamin D precursors, sunlight exposure is the primary determinant of vitamin D status in humans. However, in northern latitudes between November and March there are insufficient UV-B rays to produce vitamin D. Moreover, sunscreen use in childhood, which protects against future melanoma, decreases vitamin D production in the skin. Together, these factors contribute to the recent reports of hypovitaminosis D in diverse populations.

There is controversy, however, about what a healthy level of 25-hydroxyvitamin D (25(OH)D) is for children and even what level of 25(OH)D should be used to define vitamin D deficiency. In 1997, the Institute of Medicine defined vitamin D deficiency as a serum 25(OH)D level of <20 nmol/L (to convert to ng/mL divide by 2.496). In 2007, the Canadian Paediatric Society defined vitamin D deficiency as a serum 25(OH)D level of <25 nmol/L. Also, in a 2008 review written on behalf of the Lawson Wilkins Pediatric Endocrine Society, vitamin D deficiency was defined as a serum 25(OH)D level of <37.5 nmol/L. Although investigators’ definitions differ and different laboratory assays have been used to determine serum 25(OH)D levels, the preponderance of evidence from single-center studies suggests widespread hypovitaminosis D in children of all ages. A nationally representative study of children aged ≥12 years from 1988–1994, using an even stricter criterion for deficiency (<17.5 nmol/L), found little evidence of deficiency, but found that lesser degrees of vitamin D deficiency are common. And there is a growing interest in these lesser degrees of vitamin D deficiency. Indeed, an examination of the 2000–2004 National Health and Nutrition Examination Survey (NHANES) shows, among other data, the percentage of males and females 0 to 70 years of age with a 25(OH)D level of <50 nmol/L.

Although controversial, higher levels of 25(OH)D have been shown in some studies to improve bone health and also may help prevent cancer, autoimmune diseases/type 1 diabetes, infectious diseases, myocardial infarction, and childhood wheezing. In adults, emerging data suggest that the optimal level of 25(OH)D may be as high as 75 or 100 nmol/L. In children, the optimal level of serum 25(OH)D for general health is unknown and even more controversial then in adults, because there are fewer outcome data.

Our objective was to determine the prevalence of serum 25(OH)D levels of <25, ≤50, and <75 nmol/L in a nationally representative sample of US children aged 1 to 11 years.

METHODS

Study Design and Participants

Annually, the National Center for Health Statistics conducts the NHANES, a nationally representative probability sample of the noninstitutionalized US civilian population. Since 1999, NHANES data were released in 2-year cycles. We received a waiver from our institutional review board and analyzed the 2 most recent cycles of NHANES data (ie, January 2001 to December 2004).

Details of survey methodology are described elsewhere. Briefly, the sample was obtained by using a complex, stratified, multistage probability study design with unequal probabilities of selection. The NHANES oversamples certain subgroups of people including low-income persons, black persons, and Mexican Americans. The NHANES uses a 4-stage sampling strategy covering geographic primary sampling units, which are counties or small groups of contiguous counties, segments within primary sampling units (a block or group of blocks), households within segments, and 1 or more participants within households.

Serum 25(OH)D levels were obtained for participants aged 6 to 11 years from 2001–2004 and for those aged 1 to 5 years from 2003 to 2004. During 2001–2004, the NHANES collected household interview data for 2276 (87%) of 2630 invited participants aged 6 to 11. Subsequently, 2194 (96%) participants received physical and laboratory examination in a mobile examination center (MEC), of which 1837 had serum 25(OH)D testing (357 missing). During 2003–2004, the NHANES collected household interview data for 1267 (88%) of 1447 invited participants aged 1 to 5. Subsequently, 992 (78%) participants had MEC evaluation, of which 885 had serum 25(OH)D testing (97 missing).

Data Collection

Throughout the NHANES years, strategies for sampling and methodologies for data collection were very similar to maintain consistency and facilitate comparisons. To avoid weather issues and improve response, the NHANES MECs preferentially scheduled data collection in the lower latitudes (farther south) during winter months and higher latitudes (farther north) during the summer months. Demographic data (age, gender, race/ethnicity), based on self-report, were recorded. The poverty/income ratio is provided in the NHANES data set and was used to control for socioeconomic status; values of <1 were considered low socioeconomic status. For the vitamin supplement data, the participant showed the interviewer all of the vitamin/mineral supplements being used. The interviewer recorded the information...
and asked about frequency of use. Later, trained nutritionists matched each supplement to the National Center for Health Statistics database, which contained detailed information about ingredients. We recorded the vitamin D dosage for all supplements and the frequency of use. The results are stratified by those who were and were not taking vitamin D–containing supplements.

Blood samples for serum 25(OH)D testing collected during the examination were centrifuged, aliquoted, and frozen to −70°C on-site, and shipped on dry ice to central laboratories where they were stored at −70°C until analysis. Serum 25(OH)D levels were measured by a radioimmunoassay kit after extraction with acetonitrile (DiaSorin, Stillwater, MN) by the National Center for Environmental Health (Atlanta, GA).

### Results

#### Analysis

We performed statistical analyses by using Stata 9.0 (Stata Corp, College Station, TX). Using survey commands, we applied the recommended subsample weights for the interview plus examination data to account for unequal probabilities of selection. The NHANES provides weighting of the actual number of subjects to allow for the sample to represent the entire US population on the basis of census statistics. We used these weights to provide population estimates of 25(OH)D levels. Although all of results are presented as weighted values, we also provide the raw numbers to allow for insight about the sample size. We calculated variance on the basis of NHANES-provided masked variance units by using the Taylor series linearization method. We categorized serum 25(OH)D levels as <25, <50, and <75 nmol/L. Primary analysis is descriptive with 95% confidence intervals (CIs). We tested for interactions by using logistic regression using interaction terms for age and race/ethnicity while controlling for the primary effects of age, gender, and race/ethnicity.

#### Results

During 2001–2004, the mean serum 25(OH)D for children aged 1 to 11 years was 70 nmol/L. Using the NHANES weighting of the actual number of subjects to provide population estimates, there were 45 participants with serum 25(OH)D levels of <25 nmol/L, representing 250 000 (95% CI: 120 000–390 000) children; 677 participants with a serum 25(OH)D level of <50 nmol/L, representing 5.1 million (95% CI: 4.2–5.9 million) children; and 2073 participants with a serum 25(OH)D level of <75 nmol/L, representing 22 million (95% CI: 20–25 million) children. Overall, the prevalence of serum 25(OH)D levels of <25 nmol/L was 0.7% (95% CI: 0.4–1.3), <50 nmol/L was 15% (95% CI: 12–18), and <75 nmol/L was 65% (95% CI: 58–71).

#### Demographics

Fig 1 shows the prevalence of serum 25(OH)D levels for all of the children as a group (ie, everyone aged 1 to 11 years) at 3 thresholds: <25, <50, and <75 nmol/L. Although the prevalence of children aged 1 to 11 years with a serum 25(OH)D level of <25 nmol/L is not high (0.7%), non-Hispanic black children (3.6%) clearly have the highest percentage. When the Institute of Medicine’s definition of deficiency (<27.5 nmol/L) is used, the prevalence of vitamin D deficiency increases to 1.1% for all children aged 1 to 11 years. When the threshold of <50 nmol/L is used a substantial proportion of children have low levels of serum 25(OH)D. If a serum 25(OH)D level of <75 nmol/L is used, the prevalence of children aged 1 to 11 years in this category is higher among girls (67% [95% CI: 60–73]) compared with boys (62% [95% CI: 55–69]), and non-Hispanic black (89% [95% CI: 85–92]) and Mexican American children (77% [95% CI: 74–79]) compared with non-Hispanic white children (54% [95% CI: 45–62]). Adjustment for socioeconomic status, as measured by poverty/income ratio, did not materially change these results (data not shown). Mean and categorical 25(OH)D levels stratified by age are presented in the Table 1, because the mean levels of 25(OH)D were lower in children aged 6 to 11 years (68 nmol/L [95% CI: 65–70])
The vitamin D dosage was 200 IU for 8.7%, 100 IU for 8.7%, and 400 IU for 88% of participants. The prevalence of 25(OH)D levels at 50–74.9 nmol/L (75 nmol/L) was reported for 53% of participants, and these supplements were used to treat vitamin D deficiency.8 The initial definitions and discussion about a healthy level of vitamin D are crucial for determining thresholds for vitamin D deficiency and sufficiency.2,3

**Discussion**

To our knowledge, this is the first nationally representative sample providing an in-depth examination of the prevalence of 3 levels of serum 25(OH)D (<25, <50, and <75 nmol/L) in children aged 1 to 11 years. These data highlight that millions of children in the United States have levels of 25(OH)D that are too low and that non-Hispanic black and Mexican American children have the lowest levels of 25(OH)D. Practitioners caring for children should become aware of the diverse health effects of vitamin D and understand that this group of children may require more vitamin D than is currently being used or consumed in their diet (including supplements).

In children, there are sparse outcome data to help define a healthy or optimal level of 25(OH)D. Although vitamin D deficiency has been defined as a child having a serum 25(OH)D level of <25 nmol/L10 or <27.5 nmol/L8, some have proposed that levels of <50 nmol/L should define vitamin D deficiency.8,13 The initial definitions and discussion about a healthy level of vitamin D concerned the prevention of rickets.8 Data, however, demonstrate that vitamin D is a hormone with receptors throughout the body.40 As a result, health outcomes beyond rickets are now being considered when experts and national panels try to define a healthy level of 25(OH)D for children.41

In terms of bone-related outcomes, Gordon et al22 recently demonstrated...
that one third of infants and toddlers with a serum 25(OH)D level of <50 nmol/L were noted to have some evidence of bone demineralization by standard radiograph. In addition, mild rickets has been found in North American infants with serum 25(OH)D levels close to 50 nmol/L.42 Considering nonbone health outcomes, a meta-analysis shows that the risk of type 1 diabetes is significantly reduced in children receiving vitamin D supplements compared with those not receiving supplements.29 Respiratory outcomes have also been investigated. Children aged 2 to 60 months hospitalized with acute lower respiratory tract infection had a 12.5-fold higher unadjusted odds of having a serum 25(OH)D level of <50 nmol/L compared with healthy controls.43 Two prospective birth cohorts, 1 from the United States34 and 1 from Scotland35 have both demonstrated that lower maternal intake of vitamin D during pregnancy is associated with increased risk of recurrent wheezing in these mothers’ children. Combining the infection and wheezing outcomes, Camargo et al44 found in a birth cohort of 922 New Zealand children an inverse relationship between the level of 25(OH)D in umbilical cord blood and parent-reported respiratory infection (ie, bronchiolitis, croup, pneumonia, throat infections, and ear infections) by 3 months of age and parent-reported wheezing illness at 15 months, 3 years, and 5 years of age. These results were independent of season, exclusive breastfeeding, and other potentially relevant confounders. The risk was lowest for children with a cord blood 25(OH)D level of ≥75 nmol/L.44 Unlike the bone outcomes, the mechanism underlying the association with vitamin D and risk of infections is less clear, although the innate immune system seems to play a role.45 In adults, there is more data describing the nonbone health effects of vitamin D.* Two recently published studies33,48 demonstrate that a healthy level of 25(OH)D may be at least 75 nmol/L. In 1 study, patients with colorectal cancer who had mean 25(OH)D levels of >100 nmol/L were almost 50% less likely to die (from all causes, including colon cancer) than those with a mean serum 25(OH)D level of <42 nmol/L.48 In another recent prospective study, the risk of myocardial infarction increased as a man’s serum 25(OH)D level decreased. Men with serum 25(OH)D levels of <37.5 nmol/L had a 2.4 relative risk increase in myocardial infarction compared with men with serum 25(OH)D levels of ≥75 nmol/L after controlling for multiple other risk factors.35 Adult data frequently do not translate to children, and the clinical outcomes examined in many of the adult vitamin D studies are not relevant for children. Nonetheless, these adult data should not be ignored by clinicians caring for children, because results from both adult and pediatric studies similarly suggest that healthier levels of 25(OH)D may prove to be 50, 75, or even >75 nmol/L.

The level of concern regarding the national prevalence data presented here will depend, in part, on what level of 25(OH)D is eventually found to be optimal for a child’s health. The Canadian Paediatric Society has termed children with levels of 25(OH)D of <75 nmol/L as insufficient.18 When this 75 nmol/L level is applied to US children aged 1 to 11 years, 2 of every 3 children in the United States are below this threshold and almost all non-Hispanic black and Mexican American children are below this threshold. If the threshold is changed to <50 nmol/L, then almost half of non-Hispanic black children aged 6 to 11 years fall into this category. Considering these prevalence data, would there be risks associated with recommending that all children

*Refs 23–28, 30–32, 34, 35, 43, 46, and 47.
The present study has some potential limitations. We did not analyze latitude and season in this analysis, the most important determinants of the serum level of 25(OH)D. For these NHANES data, serum was collected at only 1 point in time and preferentially collected in northern states in the summer and southern states in the winter. Therefore, this geographical preference used for the sampling may slightly increase overall population 25(OH)D levels and, as a result, these data most likely represent the “best-case” scenario for 25(OH)D levels. If, therefore, this geographical preference for sampling may slightly increase overall population levels of 25(OH)D would be even greater. Another potential limitation is that demographic and vitamin supplementation information is self-report, and other factors associated with 25(OH)D levels were not analyzed (eg, estimated sunlight exposure and diet). However, the purpose of our analysis was to examine the prevalence of certain levels of 25(OH)D in children and not to predict or determine the cause of the observed levels.

**CONCLUSIONS**

There are millions of children with levels of 25(OH)D lower than some experts believe to be healthy, especially among non-Hispanic black and Mexican American children. These data are a call to action to determine in children the optimal level of serum 25(OH)D, the health effects of vitamin D in children, and the different approaches that one might use to reach a healthy level. In the meantime, however, on the basis of the limited risk of toxicity, we conclude that it is likely that many US children need more vitamin D.
