This article is a chapter in the ISPAD Clinical Practice Consensus Guidelines 2014 Compendium. The complete set of guidelines can be found for free download at www.ispad.org. The evidence grading system used in the ISPAD Guidelines is the same as that used by the American Diabetes Association. See page 3 (the Introduction in Pediatric Diabetes 2014; 15 (Suppl. 20): 1-3).

Executive summary and Recommendations

The biochemical criteria for the diagnosis of diabetic ketoacidosis (DKA) are:

- Hyperglycemia [blood glucose (BG) >11 mmol/L (≈200 mg/dL)]
- Venous pH < 7.3 or bicarbonate <15 mmol/L
- Ketonemia and ketonuria.

The clinical signs of DKA include:

- Dehydration (which may be difficult to detect)
- Tachycardia
- Tachypnea (which may be mistaken for pneumonia or asthma)
- Deep, sighing (Kussmaul) respiration; breath has the smell of acetone (variously described as the odor of nail polish remover or rotten fruit)
- Nausea, vomiting (which may be mistaken for gastroenteritis)
- Abdominal pain that may mimic an acute abdominal condition
- Confusion, drowsiness, progressive reduction in level of consciousness and, eventually, loss of consciousness.

Risk factors for DKA in newly diagnosed cases include younger age (<2 yr), delayed diagnosis, lower socioeconomic status, and countries with low prevalence of type 1 diabetes mellitus.
Risk factors for DKA in patients with known diabetes include insulin omission, poor metabolic control, previous episodes of DKA, gastroenteritis with persistent vomiting and inability to maintain hydration, psychiatric (including eating) disorders, challenging social and family circumstances, peripubertal and adolescent girls, limited access to medical services, failures in insulin pump therapy.

The following recommendations are based on currently available evidence and are intended only as a general guide to DKA management. Because there is considerable individual variability in presentation of DKA (ranging from mild with only minimal dehydration to severe with profound dehydration), some patients may require specific treatment that, in the judgment of the treating physician, may be within or, occasionally, outside the range of options presented here. Clinical judgment should always be used to determine optimal treatment of the individual patient, and timely adjustments to treatment (insulin dose, electrolyte composition and rate of infusion of rehydration fluids) should be based on ongoing, careful clinical and biochemical monitoring of the patient’s response.

Emergency assessment should follow the general guidelines for Pediatric Advanced Life Support (PALS) and includes: immediate measurement of BG, blood or urine ketones, serum electrolytes, blood gases and full blood count; assessment of severity of dehydration and level of consciousness (E). A second peripheral IV catheter should be inserted (E).

Management should be in centers experienced in the treatment of DKA in children and adolescents and where vital signs, neurological status and laboratory results can be monitored frequently (E). Where geographic constraints require that management be initiated in a center with less experience and with fewer resources, there should be arrangements in place for telephone or videoconference support from a physician with expertise in DKA (E).

Meticulous monitoring of the clinical and biochemical response to treatment is necessary so that timely adjustments in treatment can be made when indicated by the patient’s clinical or laboratory data (E).

Goals of therapy are to correct dehydration, correct acidosis and reverse ketosis, slowly correct hyperosmolality and restore BG to near normal, monitor for complications of DKA and its treatment, and identify and treat any precipitating event.

Fluid replacement should begin before starting insulin therapy. Expand volume, as required, to restore peripheral circulation (E). Calculate the subsequent rate of fluid administration, including the provision of maintenance fluid requirements, aiming to replace the estimated fluid deficit evenly over 48 h. The rate of fluid administration should seldom exceed 1.5–2 times the usual daily maintenance requirement (C).

Insulin therapy: begin with 0.05–0.1 U/kg/h 1–2 h AFTER starting fluid replacement therapy (C, B).

Potassium: If the patient is hyperkalemic, defer potassium replacement therapy until urine output is documented. Otherwise, begin with 40 mmol potassium/L in the infusate or 20 mmol potassium/L in the patient receiving fluid at a rate >10 mL/kg/h (E).

Bicarbonate administration is not recommended except for treatment of life-threatening hyperkalemia (B).

Warning signs and symptoms of cerebral edema include: headache (variable severity) and slowing of heart rate, change in neurological status (restlessness, irritability, increased drowsiness, incontinence), specific neurological signs (e.g., cranial nerve palsies), rising blood pressure and decreased oxygen saturation.

In patients with multiple risk factors for cerebral edema, have mannitol or hypertonic saline at the bedside and the dose to be given calculated beforehand (E). If neurologic status deteriorates acutely, hyperosmolar therapy should be given immediately (C).

Prevention: Management of an episode of DKA is not complete until an attempt has been made to identify and treat the cause. Recurrent DKA without a preceding febrile or vomiting illness is almost always the result of psychosocial problems and failure to take insulin (E).

The criteria for hyperglycemic hyperosmolar state (HHS) include:

- Plasma glucose concentration >33.3 mmol/L (600 mg/dL)
- Venous pH > 7.25; arterial pH > 7.30
- Serum bicarbonate >15 mmol/L
- Small ketonuria, absent to mild ketonemia
- Effective serum osmolality >320 mOsm/kg
- Altered consciousness (e.g., obtundation, combativeness) or seizures.

In HHS, the goals of initial fluid therapy are to expand the intra- and extravascular volume, restore normal renal perfusion and promote a gradual decline in serum sodium concentration and osmolality.

In HHS, insulin administration should begin at a dose of 0.025 to 0.05 U/kg/h once plasma glucose is no longer declining at a rate of at least 3 mmol/L (50 mg/dL) per hour with fluid alone (C).

Diabetic ketoacidosis (DKA) results from deficiency of circulating insulin and increased levels of the counterregulatory hormones: catecholamines, glucagon,
cortisol and growth hormone (1, 2). Severe insulin deficiency occurs in previously undiagnosed type 1 diabetes mellitus and when patients on treatment deliberately or inadvertently do not take insulin, especially the long-acting component of a basal-bolus regimen. Patients who use an insulin pump can rapidly develop DKA when insulin delivery fails for any reason (3). Relative insulin deficiency occurs when the concentrations of counterregulatory hormones markedly increase in response to stress in conditions such as sepsis, trauma, or gastrointestinal illness with diarrhea and vomiting, which overwhelm homeostatic mechanisms and lead to metabolic decompensation despite the patient taking the usual recommended dose of insulin.

The combination of absolute or relative insulin deficiency and high counterregulatory hormone concentrations results in an accelerated catabolic state with increased glucose production by the liver and kidney (via glycogenolysis and gluconeogenesis), and simultaneously impaired peripheral glucose utilization, which combine to result in hyperglycemia and hyperosmolality; insulin deficiency and high counterregulatory hormones also increase lipolysis and ketogenesis and cause ketonemia and metabolic acidosis. Hyperglycemia that exceeds the usual renal threshold of approximately 10 mmol/L (180 mg/dL) (the range in normal and diabetic individuals varies) together with hyperketonemia cause osmotic diuresis, dehydration, and obligatory loss of electrolytes, often aggravated by vomiting associated with severe ketosis. These changes stimulate further stress hormone production, which induces more severe insulin resistance and worsening hyperglycemia and hyperketonemia. If this cycle is not interrupted by exogenous insulin as well as fluid and electrolyte therapy, fatal dehydration and metabolic acidosis will ensue. Lactic acidosis from hypoperfusion or sepsis contributes to the acidosis (4) (Fig. 1).

DKA is characterized by severe depletion of water and electrolytes from both the intra- and extracellular fluid (ECF) compartments; the range of losses is shown in Table 1. Despite their dehydration, patients generally continue to maintain normal or even have high blood pressure (5), possibly due to elevated plasma catecholamine concentrations, increased release of antidiuretic hormone (ADH) in response to hyperosmolality, which increases blood pressure via V2 receptors, or other factors (5). Considerable urine output persists because of glucosuria until extreme volume depletion leads to a critical decrease in renal blood flow and glomerular filtration. At presentation, the specific deficits in an individual patient vary depending upon the duration and severity of illness, the extent to which the patient was able to maintain intake of fluid and electrolytes, and the content of food and fluids consumed before coming to medical attention. Consumption of fluids with a high-carbohydrate content (juices or sugar containing soft drinks) may exacerbate the hyperglycemia (6). Rapid emptying of stomach contents containing an abundant quantity of sugar, which occurs as gastroparesis is relieved with therapy, accounts for the rise in plasma glucose concentration observed in some patients after onset of therapy despite ongoing large loss of glucose in the urine (7).

Data are from measurements in only a few children and adolescents (8–12). In any individual patient, actual losses may be less or greater than the ranges shown in Table 1.

Three methods for determining maintenance water requirements in children are commonly used: the Holliday-Segar formula (13), a simplified Holliday-Segar formula (Simplified method based on Holliday-Segar: <10 kg 4 mL/kg/h; 11–20 kg 40 + 2 mL/kg/h for each kg between 11 and 20; >20 kg 60 + 1 mL/kg/h for each kg >20), and a formula based on body surface area for children more than 10 kg (1500 mL/m²/24 h) (14).

†Maintenance electrolyte requirements in children are per 100 mL of maintenance IV fluid (14, 15).

Clinical manifestations of DKA
- Dehydration
- Tachypnea; deep, sighing (Kussmaul) respiration
- Nausea, vomiting, and abdominal pain that may mimic an acute abdominal condition
- Confusion, drowsiness, progressive obtundation and loss of consciousness

Table 2 shows the volume of maintenance and replacement fluid volumes (based on body weight and an assumption of 10% dehydration) according to Darrrow (16).

Definition of diabetic ketoacidosis (DKA)
The biochemical criteria for the diagnosis of DKA are (17):
- Hyperglycemia [BG >11 mmol/L (≈200 mg/dL)]
- Venous pH < 7.3 or bicarbonate <15 mmol/L
- Ketonemia* and ketonuria.

*Although not universally available, blood β-hydroxybutyrate (BOHB) concentration should be measured whenever possible; a level ≥3 mmol/L is indicative of DKA (18).

Urine ketones are typically ≥2+ (‘moderate or large’) positive. Partially treated children and children who have consumed little or no carbohydrate may rarely have only modestly elevated BG concentrations, referred to as ‘euglycemic ketoacidosis’ (19, 20).

Type 2 diabetes mellitus in the pediatric age range is increasing in frequency. The worldwide incidence and prevalence of type 2 diabetes in children and adolescents vary substantially among countries, age categories and ethnic groups, which can be explained by variations in population characteristics and methodological dissimilarities between studies (21). At some centers in the USA, type 2 diabetes now accounts for up to one half of newly diagnosed diabetes in children aged 10–21 yr (22). The SEARCH for Diabetes in Youth Study in the USA found that nearly 10% of youth with type 2 diabetes presented with DKA (23); however, overall, 5–25% of patients with type 2 diabetes have DKA at the time of diagnosis (24).

The severity of DKA is categorized by the degree of acidosis (25):
- Mild: venous pH < 7.3 or bicarbonate <15 mmol/L
- Moderate: pH < 7.2, bicarbonate <10 mmol/L
- Severe: pH < 7.1, bicarbonate <5 mmol/L

HHS, formerly referred to as hyperosmolar nonketotic coma, may occur in young patients with type 2 diabetes (26–28), in type 1 diabetes subjects (29) and in infants, especially those with 6q24-related transient neonatal diabetes mellitus (30). The criteria for HHS include (31, 32):
- Plasma glucose concentration >33.3 mmol/L (600 mg/dL)
- Arterial pH > 7.30; venous pH > 7.25
- Serum bicarbonate >15 mmol/L
- Small ketonuria, absent to small ketonemia1
- Effective serum osmolality >320 mOsm/kg
- Obtundation, combativeness, or seizures (in approximately 50%).

It is important to recognize that the overlap between the characteristic features of HHS and DKA may occur, and some patients with HHS, especially when there is severe dehydration, have mild or moderate acidosis that is mainly due

1Nitroprusside reaction method.

DKA, diabetic ketoacidosis.

After initial resuscitation, and assuming 10% dehydration, the total amount of fluid should be given over 48 h. Table 2 shows volumes for maintenance and rehydration per 24 h and per hour. Fluids given orally (when patient has improved) should be subtracted from the amount in the table. Table 2 is based on maintenance volumes according to Darrow (16). For body weights >32 kg, the volumes have been adjusted so as not to exceed twice the maintenance rate of fluid administration. Example: A 6-yr-old boy weighing 20 kg will receive 10 mL/kg (or 200 mL) in the first 1-2 h and thereafter 93 mL/h or a total volume of 2230 mL/24 h for 48 h.

to hypoperfusion/lactic acidosis. Conversely, some children with type 1 diabetes may have features of HHS (severe hyperglycemia) especially if high carbohydrate containing beverages have been used to quench thirst and replace urinary losses before diagnosis (6). Therapy must be appropriately modified to address the pathophysiology and particular biochemical disturbances of the individual patient (see below). See page 16 regarding specific therapy of HHS.

Frequency of DKA

At disease onset

There is wide geographic variation in the frequency of DKA at onset of diabetes; rates inversely correlate with the regional incidence of type 1 diabetes. Frequencies range from approximately 15–70% in Europe and North America (23, 33–38). DKA at diagnosis is more common in younger children (<2 yr of age), often the consequence of diagnostic error or delayed treatment (39–41), those from ethnic minority groups, and in children whose families do not have ready access to medical care for social or economic reasons (20, 23, 37, 39, 42, 43).

In children with established diabetes

The risk of DKA in established type 1 diabetes is 1–10% per patient per year (3, 44–48):

Risk is increased in (47):

- Children who omit insulin (46).
- Children with poor metabolic control or previous episodes of DKA.
- Gastroenteritis with persistent vomiting and inability to maintain hydration.
- Children with psychiatric disorders, including those with eating disorders.
- Children with difficult or unstable family circumstances (e.g., parental abuse).
- Peripubertal and adolescent girls.
- Children with limited access to medical services.
- Insulin pump therapy (as only rapid- or short-acting insulin is used in pumps, interruption of insulin delivery for any reason rapidly leads to insulin deficiency) (3, 49).

In recurrent DKA, insulin omission or failure to follow sick day or pump failure management guidelines accounts for almost all episodes.

Management of DKA (Figure 2)

Emergency assessment

Acute management should follow the general guidelines for PALS (50, 51), with particular attention to the following aspects for the child who presents in DKA.

- Immediately measure BG and blood BOHB (or urine ketone) concentrations with bedside meters. Perform a clinical evaluation to identify a possible infection.
  - Measurement of blood BOHB concentration with a point-of-care meter, if available, is useful to
confirm ketoacidosis ($\geq 3$ mmol/L in children) (18) and to monitor the response to treatment (52–58).

- **Weigh** the patient. If body surface area is used for fluid therapy calculations, measure height or length to determine surface area. The current weight should be used for calculations and not the weight from a previous office visit or hospital record.

- **Assess severity of dehydration.**
  - Estimation of the degree of dehydration is imprecise and generally shows only fair to moderate agreement among examiners (59–61). It should be based on a combination of physical signs. The three most useful individual signs for predicting 5% dehydration in young children aged 1 month to 5 yr are:
    - Prolonged capillary refill time (normal capillary refill is $\leq 1.5–2$ s)
    - Abnormal skin turgor (‘tenting’ or inelastic skin)
    - Abnormal respiratory pattern (hyperpnea) (62).
  - Other useful signs in assessing degree of dehydration include: dry mucus membranes, sunken eyes, absent tears, weak pulses, and cool extremities. More signs of dehydration tend to be associated with more severe dehydration (62).
  - $\geq 10\%$ dehydration is suggested by the presence of weak or impalpable peripheral pulses, hypotension, and oliguria.

- **Assess level of consciousness** [Glasgow coma scale (GCS) – see Table 3] (63).
- **Obtain a blood sample for laboratory measurement of:**
  - Serum or plasma glucose
  - Electrolytes (including bicarbonate)
  - Blood urea nitrogen, creatinine
  - Serum osmolality
  - Venous pH, pCO$_2$
  - Hemoglobin, hematocrit and complete blood count. Note that an increased white blood cell count in response to stress is characteristic of DKA and is not indicative of infection (64)
  - Albumin, calcium, phosphorus, magnesium concentrations (if possible).

- Although not essential for management of DKA *per se*, hemoglobin Alc (HbAlc) may be useful in the evaluation and management of specific patients as it provides information about the duration of hyperglycemia.
- **Perform a urinalysis** for ketones.
- Obtain appropriate *specimens for culture* (blood, urine, and throat), only if there is evidence of infection (e.g., fever).
- If laboratory measurement of serum potassium is delayed, perform an *electrocardiogram* (ECG) for baseline evaluation of potassium status (65, 66).

**Additional measures**

For the pediatric patient who presents with a hyperglycemic crisis, the following aspects of emergency care warrant particular attention:

- **Secure the airway** and empty the stomach by continuous nasogastric suction to prevent pulmonary aspiration in the unconscious or severely obtunded patient.

</tbody>
</table>

The GCS consists of three parameters and is scored between 3 and 15; 3 being the worst and 15 the best (63). One of the components of the GCS is the best verbal response, which cannot be assessed in non-verbal young children. A modification of the GCS was created for children too young to talk. Inappropriate words, random or exclamatory articulated speech, but no sustained conversational exchange.

$^*_{Attention}$ can be held; patient responds to questions coherently, but there is some disorientation and confusion.
Intubation should be avoided if possible; a sudden increase of pCO$_2$ during or following intubation may cause cerebrospinal fluid (CSF) pH to decrease and contribute to worsening of cerebral edema (67).

If there is a history of recent large consumption of glucose-containing fluids, consider emptying the stomach even in the patient who is not obtunded.

When large quantities of fruit juice or sweetened soft drinks have been ingested, the stomach may contain a large volume of water with little sodium. Gastric emptying early in the course of therapy leads to absorption of glucose and electrolyte-free water from the intestinal tract (7, 68).

Give oxygen to patients with severe circulatory impairment or shock.

A cardiac monitor should be used for continuous electrocardiographic monitoring to assess T waves for evidence of hyper- or hypokalemia (65, 66).

A second peripheral intravenous (IV) catheter should be placed for convenient and painless repetitive blood sampling. An arterial catheter may, rarely, be necessary in some critically ill patients managed in an intensive care unit.

Unless absolutely necessary, avoid placing a central venous catheter because of the high risk of thrombosis, especially in the very young; if a central catheter has been inserted, remove it as soon as the patient’s clinical status permits (69, 70).

Insulin should preferably not be given through a central line unless it is the only available option because its infusion may be interrupted when other fluids are given through the same line.

Give antibiotics to febrile patients after obtaining appropriate cultures of body fluids.

Catheterization of the bladder usually is not necessary, but if the child is unconscious or unable to void on demand (e.g., infants and very ill young children) the bladder should be catheterized.

Where should the child with DKA be managed?

The child should receive care in a unit that has:

- Experienced nursing staff trained in monitoring and management of DKA in children and adolescents.
- Written guidelines for DKA management in children.
- Access to a laboratory that can provide frequent and timely measurements of biochemical variables.

Whenever possible, a specialist/consultant pediatrician with training and expertise in the management of DKA should direct inpatient management. Where geographic constraints require that management be initiated in a center with less experience and with fewer resources, there should be arrangements in place for telephone or videoconference support from a physician with expertise in DKA.

Children with severe DKA (long duration of symptoms, compromised circulation, or depressed level of consciousness) or those who are at increased risk of cerebral edema (e.g., <5 yr of age, severe acidosis, low pCO$_2$, high blood urea nitrogen) should be considered for immediate treatment in an intensive care unit (pediatric if available) or in a unit that has equivalent resources and supervision, such as a children’s ward specializing in diabetes care (17, 71).

In a child with established diabetes, whose parents have been trained in sick day management, hyperglycemia and ketosis without vomiting or severe dehydration can be managed at home or in an outpatient health care facility (e.g., emergency ward), provided an experienced diabetes team supervises the care (25, 72, 73).

Clinical and biochemical monitoring

Successful management of DKA and HHS requires meticulous monitoring of the patient’s clinical and biochemical response to treatment so that timely adjustments in treatment can be made when indicated by the patient’s clinical or laboratory data.

There should be documentation on a flow chart of hour-by-hour clinical observations, IV and oral medications, fluids, and laboratory results. Monitoring should include the following:

- Hourly (or more frequently as indicated) vital signs (heart rate, respiratory rate, blood pressure).
- Hourly (or more frequently as indicated) neurological observations (GCS; Table 3) for warning signs and symptoms of cerebral edema (see below).

- Headache
- Inappropriate slowing of heart rate
- Recurrence of vomiting
- Change in neurological status (restlessness, irritability, increased drowsiness, incontinence) or specific neurologic signs (e.g., cranial nerve palsies, abnormal pupillary responses)
- Rising blood pressure
- Decreased oxygen saturation
- Rapidly increasing serum sodium concentration suggesting loss of urinary free water as a manifestation of diabetes insipidus (from
interruption of blood flow to the pituitary gland due to cerebral herniation).

- Amount of administered insulin.
- Hourly (or more frequently as indicated) accurate fluid input (including all oral fluid) and output.
- **Capillary blood glucose** concentration should be measured hourly (but must be cross-checked against laboratory venous glucose, as capillary methods may be inaccurate in the presence of poor peripheral circulation and acidosis).

  - **Laboratory tests**: serum electrolytes, glucose, blood urea nitrogen, calcium, magnesium, phosphorus, hematocrit, and blood gases should be repeated 2–4 h, or more frequently, as clinically indicated, in more severe cases.

- Blood BOHB concentrations, if available, every 2 h (53–57).
  - Near-patient (also referred to as point-of-care) BOHB measurements correlate well with a reference method up to 3 mmol/L, but are not accurate above 5 mmol/L (55, 74).

- Lipids and triglycerides can be grossly elevated causing the blood sample to show a visible rim of lipids (75).

- If the laboratory cannot provide timely results, a portable biochemical analyzer that measures serum electrolytes and blood gases on fingerstick blood samples at the bedside is a useful adjunct to laboratory-based determinations. BG and blood or urine ketone concentrations can be measured with a bedside meter while awaiting results from the laboratory.

- **Calculations**:
  - Anion gap = Na – (Cl + HCO₃⁻): normal is 12 ± 2 mmol/L.
  - In DKA, the anion gap is typically 20–30 mmol/L; an anion gap >35 mmol/L suggests concomitant lactic acidosis.
  - Corrected sodium = measured Na + 2 [(plasma glucose – 5.6)/5.6] mmol/L or measured Na + 2 [(plasma glucose – 100)/100] mg/dL.
  - Effective osmolality (mOsm/kg) = 2 × (plasma Na) + plasma glucose mmol/L (76).

**Goals of therapy**

- Correct dehydration
- Correct acidosis and reverse ketosis
- Restore BG to near normal
- Monitor for complications of DKA and its treatment
- Identify and treat any precipitating event

**Diabetic ketoacidosis and hyperglycemic hyperosmolar state**

**Fluids and salt**

Patients with DKA have a deficit in ECF volume that usually is in the range of 5–10% (8, 9). Shock with hemodynamic compromise is rare in pediatric DKA. Clinical estimates of the volume deficit are subjective and inaccurate (59–61); therefore, in moderate DKA use 5–7% and in severe DKA 7–10% dehydration. The effective osmolality (formula above) is frequently in the range of 300–350 mmol/kg. Increased serum urea nitrogen and hematocrit or hemoglobin concentration or, alternatively, plasma albumin or total protein concentration if anemia is suspected (77) are useful markers of the degree of ECF contraction (73, 78, 79), and should be determined frequently during fluid resuscitation and deficit replacement (80). The serum sodium concentration is an unreliable measure of the degree of ECF contraction for two reasons: (i) glucose, largely restricted to the extracellular space, causes osmotic movement of water into the extracellular space thereby causing dilutional hyponatremia (81, 82) and (ii) the low sodium content of the elevated lipid fraction of the serum in DKA. The latter is not a concern with most modern methods for measuring sodium. It is useful to calculate the corrected sodium (using the above formula), which represents the expected sodium concentration in the absence of hyperglycemia, and monitor its changes throughout the course of therapy. As the plasma glucose concentration decreases after administering fluid and insulin, the measured serum sodium concentration should increase and the glucose-corrected sodium concentration (formula above) should slowly decrease. It is important to appreciate that the increase in measured serum sodium concentration does not indicate a worsening of the hypertonic state. A failure of measured serum sodium levels to rise or a further decline in serum sodium levels with therapy is thought to be a potentially ominous sign of impending cerebral edema (83–85). Too rapid and ongoing rise in serum sodium concentration may also indicate possible cerebral edema as a result of loss of free water in the urine from diabetes insipidus.

The objectives of fluid and electrolyte replacement therapy are:

- Restoration of circulating volume
- Replacement of sodium and the ECF and intracellular fluid deficit of water
- Improved glomerular filtration with enhanced clearance of glucose and ketones from the blood.

**Principles of water and salt replacement**

Despite much effort to identify the cause of cerebral edema its pathogenesis is incompletely understood. There continues to be controversy concerning the
Wolfdorf et al.

association between the rate of fluid or sodium administration used in the treatment of DKA and the development of cerebral edema (86–88). No treatment strategy can be definitively recommended as being superior to another based on current evidence (87). The principles described below were developed after a comprehensive review of the literature and were accepted and endorsed by a panel of expert physicians representing the Lawson Wilkins Pediatric Endocrine Society (LWPES), the European Society for Paediatric Endocrinology (ESPE), and the International Society for Pediatric and Adolescent Diabetes (ISPAD) (17, 89).

- Water and salt deficits must be replaced.
- IV or oral fluids that may have been given in another facility before assessment should be factored into calculation of deficit and repair.

- **Resuscitation fluids** For patients who are severely volume depleted but not in shock, volume expansion (resuscitation) should begin immediately with 0.9% saline to restore the peripheral circulation. The volume administered typically is 10–20 mL/kg over 1–2 h, and may need to be repeated until tissue perfusion is adequate.
  - In the rare patient with DKA in shock, rapidly restore circulatory volume with isotonic saline in 20 mL/kg boluses infused as quickly as possible through a large bore cannula with reassessment after each bolus.
  - Use crystalloid not colloid. There are no data to support the use of colloid in preference to crystalloid in the treatment of DKA.

- **Deficit replacement fluids**

  **Subsequent** fluid management (deficit replacement) should be with an isotonic solution (0.9% saline, Ringer’s lactate or Plasmalyte) for at least 4–6 h (78, 83, 90–93).
  - Patients with mild DKA usually do not have impaired peripheral circulation and, therefore, do not require a fluid bolus. Fluid therapy should begin with deficit replacement plus maintenance fluid requirements.
  - All children will experience a decrease in vascular volume when plasma glucose concentrations fall during treatment. It is, therefore, essential to ensure that they receive sufficient fluid and salt to maintain adequate tissue perfusion.
  - Deficit replacement after 4–6 h should be with a solution that has a tonicity ≥0.45% saline with added potassium chloride, potassium phosphate, or potassium acetate (see below under potassium replacement) (78, 83, 90, 94–96). The decision to change from an isotonic to a hypotonic solution will depend on the patient’s hydration status, serum sodium concentration, and osmolality.
  - In addition to providing the usual daily maintenance fluid requirement, replace the estimated fluid deficit at an even rate over 48 h (17, 78, 97). Except for severely ill individuals, oral intake typically begins within 24 h (97). Although rehydration was planned to occur over 48 h, in a study of 635 episodes of DKA the mean time to correction of DKA and complete restoration of the circulation was 11.6 ± 6.2 h. At this point, any remaining deficits were replenished by oral intake once DKA resolved and patients were transitioned to subcutaneous (SC) insulin (97).
  - As the severity of dehydration may be difficult to determine and frequently is under- or overestimated (59–61), infuse fluid each day at a rate that seldom exceeds 1.5–2 times the usual daily maintenance requirement based on age, weight, or body surface area (17). See Table 2 for examples of calculations.
  - Satisfactory outcomes have been reported using an alternative simplified method: after an initial fluid bolus of 20 mL/kg of normal saline, 0.675% saline (3/4 normal saline, 115.5 mmol sodium) is infused at 2–2.5 times the usual maintenance rate of fluid administration regardless of the degree of dehydration, and decreased to 1–1.5 times the maintenance rate after 24 h, or earlier if acidosis resolved, until urine ketones are negative (95, 98).
  - Clinical assessment of hydration status and calculated effective osmolality are valuable guides to fluid and electrolyte therapy. The aim is gradually to reduce serum effective osmolality to normal (80, 97, 99). There should be a concomitant increase in serum sodium concentration as the serum glucose concentration decreases (sodium should rise by 0.5 mmol/L for each 1 mmol/L decrease in glucose concentration).
  - Urinary losses should not routinely be added to the calculation of replacement fluid, but this may be necessary in rare circumstances.
  - The sodium content of the fluid should be increased if measured serum sodium concentration is low and does not rise appropriately as the plasma glucose concentration falls (83, 93, 99, 100).
  - The use of large amounts of chloride-rich fluids (combined with preferential renal excretion of ketones over chloride) may be associated with the rapid development of hyperchloremia (101–103) (defined as a ratio of chloride:sodium [Cl⁻:Na⁺]...
The acidifying effect of chloride can mask recognition of resolution of ketoacidosis when total base deficit is used to monitor biochemical improvement (103).

When hyperchloremia develops, a persisting base deficit or low bicarbonate concentration can be erroneously interpreted as being due to ongoing ketosis.

To prevent this misinterpretation, measurement of bedside BOHB levels will prevent any confusion and can demonstrate that ketoacidosis has resolved. Hyperchloremic acidosis resolves spontaneously.

Although the anion gap is useful to track resolution of ketosis, it has two limitations in this setting: it is unable to differentiate a mixed metabolic acidosis (hyperchloremic and ketotic), and the degree of hyperchloremic acidosis is not quantifiable.

- Normally the difference between the serum sodium and chloride concentrations is 30–35 mmol/L. To partition the chloride component of the base deficit, the following formula has been proposed to enable clinicians to track resolution of ketoacidosis at the bedside: Chloride-induced base deficit = (plasma sodium – plasma chloride – 32) (103).
- The chloride load can be reduced by not giving potassium as potassium chloride and by using fluids such as Ringer’s lactate or Plasmalyte in which a portion of the chloride is replaced by lactate or acetate, respectively (108).

### Insulin therapy

DKA is caused by a decrease in effective circulating insulin associated with increases in counterregulatory hormone concentrations. Although rehydration alone frequently causes a marked decrease in BG concentration (109, 110), insulin therapy is essential to restore normal cellular metabolism and to normalize BG concentration and suppress lipolysis and ketogenesis (111).

There is evidence that ‘low dose’ IV insulin administration is safe and effective (97, 98, 112).

- Start insulin infusion 1–2 h after starting fluid replacement therapy; i.e., after the patient has received initial volume expansion (88).
- Correction of insulin deficiency.
  - Dose: 0.05–0.1 unit/kg/h [e.g., one method is to dilute 50 units regular (soluble) insulin in 50 mL normal saline, 1 unit = 1 mL] (113–120)
  - Route of administration IV
  - An IV bolus should not be used at the start of therapy; it is unnecessary (119, 121), may increase the risk of cerebral edema (88, 99, 122), and can exacerbate hypokalemia.

- The dose of insulin should usually remain at 0.05–0.1 unit/kg/h at least until resolution of DKA (pH > 7.30, bicarbonate > 15 mmol/L, BOHB < 1 mmol/L, or closure of the anion gap), which invariably takes longer than normalization of BG concentrations (123).
- If the patient shows marked sensitivity to insulin (e.g., some young children with DKA, patients with HHS, and some older children with established diabetes), the dose may be decreased provided that metabolic acidosis continues to resolve. For example, if a young child is receiving 0.05 unit/kg/h, it may be necessary to reduce the insulin dose to 0.03 unit/kg/h to prevent hypoglycemia.
- Uncontrolled retrospective and observational studies have reported comparable efficacy and safety using 0.05 unit/kg/h (124, 125), and some pediatric centers routinely use this dose for treatment of DKA. There are no comparative randomized controlled trial data, however, and no evidence that the higher dose is harmful.
- Insulin has an aldosterone-like effect leading to increased urinary potassium excretion (126–130). High doses administered intravenously for a prolonged period of time may contribute to a decrease in serum potassium concentration due to increased urinary potassium excretion despite potassium administration.

- Time on IV insulin infusion and dose of insulin should be minimized to avoid severe hypokalemia (131).

- During initial volume expansion, the plasma glucose concentration falls steeply (109). Thereafter, and after commencing insulin therapy, the plasma glucose concentration typically decreases at a rate of 2–5 mmol/L/h, depending on the timing and amount of glucose administration (113–116, 118, 119, 132).

- To prevent an unduly rapid decrease in plasma glucose concentration and hypoglycemia, 5% glucose should be added to the IV fluid (e.g., 5% glucose added to 0.9 or 0.45% saline) when the plasma glucose falls to approximately 14–17 mmol/L (250–300 mg/dL), or sooner if the rate of fall is precipitous.

- It may be necessary to use 10% or even 12.5% dextrose to prevent hypoglycemia while continuing to infuse insulin to correct the metabolic acidosis.
• If BG falls very rapidly (>5 mmol/L/h) after initial fluid expansion, consider adding glucose even before plasma glucose has decreased to 17 mmol/L (300 mg/dL).
• If biochemical parameters of DKA (pH, anion gap, BOHB concentration) do not improve, reassess the patient, review insulin therapy, and consider other possible causes of impaired response to insulin; e.g., infection, errors in insulin preparation.
• In circumstances where continuous IV administration is not possible and in patients with uncomplicated DKA, hourly or 2-hourly SC or intramuscular (IM) administration of a short- or rapid-acting insulin analog (insulin lispro or insulin aspart) is safe and may be as effective as IV regular insulin infusion (132–136), but should not be used in patients whose peripheral circulation is impaired.
  ◦ Initial dose SC: 0.3 unit/kg, followed 1 h later by SC insulin lispro or aspart at 0.1 unit/kg every hour, or 0.15–0.20 units/kg every 2 h.
  ◦ If BG falls to <14 mmol/L (250 mg/dL) before DKA has resolved, reduce SC insulin lispro or aspart to 0.05 unit/kg per hour to keep BG ≈ 11 mmol/L (200 mg/dL) until resolution of DKA.

Potassium replacement

Children with DKA suffer total body potassium deficits in the order of 3–6 mmol/kg (8–12). The major loss of potassium is from the intracellular pool. Intracellular potassium is depleted because of transcellular shifts of this ion caused by hypertonicity (increased plasma osmolality causes solvent drag in which water and potassium are drawn out of cells) and glycogenolysis and proteolysis secondary to insulin deficiency cause potassium efflux from cells. Potassium is lost from the body due to vomiting and as a consequence of osmotic diuresis. Volume depletion causes secondary hyperaldosteronism, which promotes urinary potassium excretion. Thus, total body depletion of potassium occurs, but at presentation serum potassium levels may be normal, increased or decreased (137). Renal dysfunction, by enhancing hyperglycemia and reducing potassium excretion, contributes to hyperkalemia (137). Administration of insulin and the correction of acidosis drive potassium back into the cells, decreasing serum levels (138). The serum potassium concentration may decrease abruptly, predisposing the patient to cardiac arrhythmias.

Replacement therapy is required regardless of the serum potassium concentration, except if renal failure is present (139, 140).

• If the patient is hypokalemic, start potassium replacement at the time of initial volume expansion and before starting insulin therapy. Otherwise, start replacing potassium after initial volume expansion and concurrent with starting insulin therapy. If the patient is hyperkalemic, defer potassium replacement therapy until urine output is documented.
• If immediate serum potassium measurements are unavailable, an ECG may help to determine whether the child has hyper- or hypokalemia (65, 66). Prolongation of the PR interval, T-wave flattening and inversion, ST depression, prominent U waves, and apparent long QT interval (due to fusion of the T and U waves) indicates hypokalemia. Tall, peaked, and symmetrical T waves and shortening of the QT interval are the signs of hyperkalemia.
• The starting potassium concentration in the infusate should be 40 mmol/L. Subsequent potassium replacement therapy should be based on serum potassium measurements.
  ◦ If potassium is given with the initial rapid volume expansion, a concentration of 20 mmol/L should be used.

• Potassium phosphate may be used together with potassium chloride or acetate; e.g., 20 mmol/L potassium phosphate and 20 mmol/L potassium acetate. Administration of potassium entirely as potassium chloride contributes to the risk of hyperchloremic metabolic acidosis, whereas administration entirely as potassium phosphate can result in hypocalcemia.
• Potential replacement should continue throughout IV fluid therapy.
• The maximum recommended rate of IV potassium replacement is usually 0.5 mmol/kg/h.
• If hypokalemia persists despite a maximum rate of potassium replacement, then the rate of insulin infusion can be reduced.

Phosphate

Depletion of intracellular phosphate occurs in DKA and phosphate is lost as a result of osmotic diuresis (8–10). Plasma phosphate levels fall after starting treatment and this is exacerbated by insulin, which promotes entry of phosphate into cells (141–143). Total body phosphate depletion has been associated with a variety of metabolic disturbances (144–146). Clinically significant hypophosphatemia may occur if IV therapy without food intake is prolonged beyond 24 h (8–10).

• Prospective studies involving relatively small numbers of subjects and with limited statistical power
Diabetic ketoacidosis and hyperglycemic hyperosmolar state have not shown clinical benefit from phosphate replacement (147–152).

- Severe hypophosphatemia combined with phosphate depletion (i.e., when not solely due to intracellular phosphate translocation) is uncommon, but can have severe consequences. Manifestations depend on the severity and chronicity of the phosphate depletion; patients usually do not have symptoms until plasma phosphate is <1 mg/dL (0.32 mmol/L).

- Severe hypophosphatemia can occur during the treatment of DKA; however, symptoms are uncommon because the hypophosphatemia is usually acute and typically there is no antecedent chronic phosphate deficiency.

- Clinical manifestations of hypophosphatemia are largely due to intracellular phosphate depletion. Decreased intracellular ATP levels impair cellular functions that depend on energy-rich phosphate compounds, and a decrease in 2,3-diphosphoglycerate (DPG) levels increases the affinity of hemoglobin for oxygen and reduces oxygen release in tissues (152). Many organ systems can be affected (145, 153). Manifestations include:
  - Metabolic encephalopathy (irritability, paresthesias, confusion, seizures, coma); impaired myocardial contractility and respiratory failure due to weakness of the diaphragm; muscle dysfunction with proximal myopathy, dysphagia, and ileus; rare hematologic effects include hemolysis, decreased phagocytosis and granulocyte chemotaxis, defective clot retraction and thrombocytopenia. Acute hypophosphatemia in a patient with preexisting severe phosphate depletion can lead to rhabdomyolysis (145, 154, 155).

- Severe hypophosphatemia associated with any of the above symptoms should be treated (156, 157).

- Administration of phosphate may induce hypocalcemia (158, 159).

- Potassium phosphate salts may be safely used as an alternative to or combined with potassium chloride or acetate, provided that careful monitoring of serum calcium is performed to avoid hypocalcemia (158, 159).

**Acidosis**

Severe acidosis is reversible by fluid and insulin replacement; insulin stops further ketoacid production and allows ketoacids to be metabolized, which generates bicarbonate. Treatment of hypovolemia improves tissue perfusion and renal function, thereby increasing the excretion of organic acids.

Controlled trials have shown no clinical benefit from bicarbonate administration (160–163). Bicarbonate therapy may cause paradoxical CNS acidosis (164, 165) and rapid correction of acidosis with bicarbonate causes hypokalemia (164, 166, 167). Bicarbonate administration may be beneficial in the rare patient with life-threatening hyperkalemia (168).

- If bicarbonate is considered necessary, cautiously give 1–2 mmol/kg over 60 min.

**Complications of therapy**

- Inadequate rehydration
- Hypoglycemia
- Hypokalemia
- Hyperchloremic acidosis
- Cerebral edema

**Introduction of oral fluids and transition to SC Insulin Injections**

- Oral fluids should be introduced only when substantial clinical improvement has occurred (mild acidosis/ketosis may still be present).

- Persistent ketonuria (measurement of urine ketones with test strips is based on the nitroprusside reaction, which measures acetoacetate and acetone) characteristically occurs for several hours after serum BOHB levels have returned to normal (53, 57).

- Absence of ketonuria should not be used as an endpoint for determining resolution of DKA.

- When oral fluid is tolerated, IV fluid should be reduced accordingly so that the sum of IV and oral fluids does not exceed the calculated IV rate (i.e., not in excess of 1.5–2 times maintenance fluid rate). This fluid restriction should be applied for 48 h from admission (72 h if there is severe hyperosmolality at onset of treatment).

- When ketoacidosis has resolved, oral intake is tolerated, and the change to SC insulin is planned, the most convenient time to change to SC insulin is just before a mealtime.

- To prevent rebound hyperglycemia, the first SC injection should be given 15–30 min (with rapid-acting insulin) or 1–2 h (with regular insulin) before stopping the insulin infusion to allow sufficient time for the insulin to be absorbed. With intermediate- or long-acting insulin, the overlap should be longer and the rate of IV insulin infusion gradually lowered. For example, for patients on a basal-bolus insulin regimen, the first dose of basal insulin may be administered in the evening and the insulin infusion is stopped the next morning.
The dose and type of SC insulin should be according to local preferences and circumstances.

After transitioning to SC insulin, frequent BG monitoring is required to avoid marked hyperglycemia and hypoglycemia.

**Morbidity and mortality**

In population studies, the mortality rate from DKA in children is 0.15–0.30% (169–171) and may be decreasing (171). Cerebral injury is the major cause of mortality and morbidity (170, 172). Cerebral edema accounts for 60–90% of all DKA deaths (85, 173). From 10–25% of survivors of cerebral edema have significant residual morbidity (85, 173, 174). Children without overt neurological symptoms during DKA treatment may have subtle evidence of brain injury, particularly memory deficits, after recovery from DKA (175).

Other rare causes of morbidity and mortality include:

- Hypokalemia*
- Hypocalcemia, hypomagnesemia
- Severe hypophosphatemia*
- Hypoglycemia
- Other central nervous system complications include dural sinus thrombosis, basilar artery thrombosis, intracranial hemorrhage, and cerebral infarction (176–178)
- Venous thrombosis (69, 70)*
- Pulmonary embolism*
- Sepsis
- Rhinocerebral or pulmonary mucormycosis (179)
- Aspiration pneumonia*
- Pulmonary edema*
- Adult respiratory distress syndrome (ARDS)
- Pneumothorax, pneumomediastinum, and SC emphysema (180)
- Rhabdomyolysis*
- Ischemic bowel necrosis
- Acute renal failure*
- Acute pancreatitis (181)*

*These complications, often with fatality, have been frequent in HHS [see (32)]. The pathophysiology and management of HHS are discussed below.

**Cerebral edema**

The incidence of clinically overt cerebral edema in national population studies is 0.5–0.9% and the mortality rate is 21–24% (85, 173, 174). Mental status abnormalities (GCS scores <14), however, occur in approximately 15% of children treated for DKA and are associated with evidence of cerebral edema on neuroimaging (182, 183). The complication is rarely seen after adolescence. Neuroimaging studies have led to the appreciation that cerebral edema is not a rare phenomenon in children with DKA, but occurs frequently with varying severity (182, 184, 185). Clinically overt cerebral edema likely represents the most severe manifestation of a common phenomenon (186).

The cause of cerebral edema is controversial. Some have explained the pathogenesis as the result of rapid fluid administration with abrupt changes in serum osmolality (100, 187–190). More recent investigations, however, have found that dehydration and cerebral hypoperfusion may be associated with DKA-related cerebral injury (85, 191–193), which have led to the formulation of an alternative hypothesis; namely, that factors intrinsic to DKA may be the cause of brain injury, which could be worsened during treatment (194, 195). It is noteworthy that the degree of edema that develops during DKA correlates with the degree of dehydration and hyperventilation at presentation, but not with factors related to initial osmolality or osmotic changes during treatment (183). Disruption of the blood–brain-barrier has been found in cases of fatal cerebral edema associated with DKA (196, 197), which further supports the view that cerebral edema is not simply caused by a reduction in serum osmolality.

Demographic factors that have been associated with an increased risk of cerebral edema include:

- Younger age (198)
- New onset diabetes (170, 198)
- Longer duration of symptoms (199)

These risk associations may reflect the greater likelihood of severe DKA.

Epidemiological studies have identified several potential risk factors at diagnosis or during treatment of DKA. These include:

- Greater hypocapnia at presentation after adjusting for degree of acidosis (85, 183, 200).
- Increased serum urea nitrogen at presentation (85, 183).
- More severe acidosis at presentation (88, 201, 202).
- Bicarbonate treatment for correction of acidosis (85, 203).
- A marked early decrease in serum effective osmolality (99, 202).
- An attenuated rise in serum sodium concentration or an early fall in glucose-corrected sodium during therapy (83–85, 202).
- Greater volumes of fluid given in the first 4 h (88, 200, 202).
- Administration of insulin in the first hour of fluid treatment (88).
Diabetic ketoacidosis and hyperglycemic hyperosmolar state

Immediate assessment

Clinical History
Polyuria
Polydipsia
Weight loss (Weigh)
Abdominal pain
Tiredness
Vomiting
Confusion

Clinical Signs
Assess dehydration
Deep sighing respiration (Kussmaul)
Smell of ketones
Lethargy/drowsiness ± vomiting

Diagnosis confirmed
Diabetic Ketoacidosis
Contact Senior Staff

Biochemical features & investigations
Ketones in urine
Elevated blood glucose
Acidemia
Blood gases, urea, electrolytes
Other investigations as indicated

Shock (reduced peripheral pulses)
Reduced conscious level/coma

Dehydration >5%
Not in shock
Acidotic (hyperventilation)
Vomiting

Mineral dehydration
Tolerating oral fluid

Resuscitation
Airway ± NG tube
Breathing (100% oxygen)
Circulation (0.9% saline 10-20 ml/kg over 1-2 h.
& repeat until circulation is restored) but do not exceed 30 ml/kg

IV Therapy
Calculate fluid requirements
Correct over 48 hours
Saline 0.9%
ECG for abnormal T-waves
Add K 40 mmol/L fluid

Continuous insulin infusion started 1-2 hours
after fluids (0.05-1 unit/kg/hour)

Critical Observations
Hourly blood glucose
Hourly fluid input & output
Neurological status at least hourly
Electrolytes 2 hourly after start of IV therapy
Monitor ECG for T-wave changes

Acidosis not improving
deterioration

Blood glucose ≤ 17 mmol/l (300mg/dL)
or
blood glucose falls >5 mmol/l/hour (90 mg/dL)

Re-evaluate
IV fluid calculations
Insulin delivery system & dose
Need for additional resuscitation
Consider sepsis

IV Therapy
Change to 0.45% saline + 5% glucose
Adjust sodium infusion to promote an
increase in measured serum sodium

Improvement
Clinically well, tolerating oral fluids

Transition to SC Insulin
Start SC insulin then stop IV insulin after an
appropriate interval

Neurological

WARNING SIGNS:
headache, slowing heart rate,
irritability, decreased
conscious level, incontinence,
specific neurological signs

Exclude hypoglycaemia
Is it cerebral edema?

Management
Give mannitol 0.5-1 g/kg or
hypertonic saline
Restrict IV fluids by one-third
Call senior staff
Move to ICU
Consider cranial imaging
only after patient stabilised

Fig. 2. Algorithm for the management of diabetic ketoacidosis. Adapted from Dunger et al. (233). NG, nasogastric; SC, subcutaneous.
Signs and symptoms of cerebral edema include:

- Headache and slowing of heart rate
- Change in neurological status (restlessness, irritability, increased drowsiness, and incontinence)
- Specific neurological signs (e.g., cranial nerve palsies, papilledema)
- Rising blood pressure
- Decreased O₂ saturation

Clinically significant cerebral edema usually develops within the first 12 h after treatment has started, but can occur before treatment has begun (85, 174, 204–207) or, rarely, may develop as late as 24–48 h after the start of treatment (85, 198, 208). Symptoms and signs are variable. Although mild to moderate headache at presentation may not be unusual (Glaser personal communication), development of a severe headache after treatment is always concerning. A method of clinical diagnosis based on bedside evaluation of neurological state is shown below (209). One diagnostic criterion, two major criteria, or one major and two minor criteria have a sensitivity of 92% and a false positive rate of only 4%. Signs that occur before treatment should not be considered in the diagnosis of cerebral edema.

**Diagnostic criteria**

- Abnormal motor or verbal response to pain
- Decorticate or decerebrate posture
- Cranial nerve palsy (especially III, IV, and VI)
- Abnormal neurogenic respiratory pattern (e.g., grunting, tachypnea, Cheyne–Stokes respiration, apneusis)

**Major criteria**

- Altered mentation/fluctuating level of consciousness
- Sustained heart rate deceleration (decrease more than 20 beats/min) not attributable to improved intravascular volume or sleep state
- Age-inappropriate incontinence

**Minor criteria**

- Vomiting
- Headache
- Lethargy or not easily arousable
- Diastolic blood pressure > 90 mmHg
- Age < 5 yr

A chart with the reference ranges for blood pressure and heart rate, which vary depending on height, weight, and gender, should be readily available, either in the patient’s chart or at the bedside.

The appearance of diabetes insipidus, manifested by increased urine output with a concomitant marked increase in the serum sodium concentration, reflecting loss of free water in the urine, is a sign of cerebral herniation causing interruption of blood flow to the pituitary gland.

**Treatment of cerebral edema**

- Initiate treatment as soon as the condition is suspected.
- Reduce the rate of fluid administration by one-third.
- Give mannitol, 0.5–1 g/kg IV over 10–15 min, and repeat if there is no initial response in 30 min to 2 h (210–212).
- Hypertonic saline (3%), suggested dose 2.5–5 mL/kg over 10–15 min, may be used as an alternative to mannitol, especially if there is no initial response to mannitol (213, 214).

- A recent 11-yr retrospective cohort study showed that hypertonic saline has replaced mannitol as the most commonly used hyperosmolar agent in many US institutions. Although further investigation is needed, the data suggest that hypertonic saline may not have benefits over mannitol and may be associated with a higher mortality rate (171).

- Hyperosmolar agents should be readily available at the bedside.
- Elevate the head of the bed to 30°.
- Intubation may be necessary for the patient with impending respiratory failure.
- After treatment for cerebral edema has been started, cranial imaging may be considered as with any critically ill patient with encephalopathy or acute focal neurologic deficit. The primary concern is whether the patient has a lesion requiring emergency neurosurgery (e.g., intracranial hemorrhage) or a lesion that may necessitate anticoagulation (e.g., cerebrovascular thrombosis) (177, 215–217).

**Hyperglycemic hyperosmolar state**

This syndrome is characterized by extreme elevations in serum glucose concentrations and hyperosmolality without significant ketosis (32). Although the incidence of HHS is increasing (27, 28, 218), it is considerably less frequent in children than DKA.

Unlike the usual symptoms of DKA (hyperventilation, vomiting and abdominal pain), which typically bring children to medical attention, the gradually increasing polyuria and polydipsia of HHS may go unrecognized resulting in profound dehydration and
electrolyte losses. In adults, fluid losses in HHS have been estimated to be twice those of DKA; furthermore, obesity and hyperosmolality can make the clinical assessment of dehydration challenging. Despite severe volume depletion and electrolyte losses, hypertonicity preserves intravascular volume, and signs of dehydration may be less evident.

During therapy, decreasing serum osmolality (from enhanced glucosuria and insulin-mediated glucose uptake) results in the movement of water out of the intravascular space resulting in decreased intravascular volume, and osmotic diuresis may continue for hours in patients with extremely increased plasma glucose concentrations. Early in the course of treatment, urinary fluid losses may be considerable. As intravascular volume may decrease rapidly during treatment in patients with HHS, more aggressive replacement of intravascular volume (as compared to treatment of children with DKA) is required to avoid vascular collapse.

**Treatment of HHS**

There are no prospective data to guide treatment of children and adolescents with HHS. The following recommendations are based on extensive experience in adults and an appreciation of the pathophysiological differences between HHS and DKA (32); see Fig. 3. Patients should be admitted to an intensive care unit or comparable setting where expert medical, nursing, and laboratory services are available.

**Fluid therapy**

The goal of initial fluid therapy is to expand the intravascular and extravascular volume and restore normal renal perfusion. The rate of fluid replacement should be more rapid than is recommended for DKA.

- The initial bolus should be $\geq 20 \text{ mL/kg}$ of isotonic saline (0.9% NaCl) and a fluid deficit of approximately 12–15% of body weight should be assumed. Additional fluid boluses should be given, if necessary, to restore peripheral perfusion.
- Thereafter, 0.45–0.75% NaCl should be administered to replace the deficit over 24–48 h.
- The goal is to promote a gradual decline in serum sodium concentration and osmolality.
- As isotonic fluids are more effective in maintaining circulatory volume, isotonic saline should be restarted if perfusion and hemodynamic status appear inadequate as serum osmolality declines.
- Serum sodium concentrations should be measured frequently and the sodium concentration in fluids adjusted to promote a gradual decline in corrected serum sodium concentration. Mortality has been associated with failure of the corrected serum sodium concentration to decline with treatment, which may be an indication for hemodialysis. Hemodialysis has resulted in 80% survival in contrast to 20% with peritoneal dialysis (28).

- Although there are no data to indicate an optimal rate of decline in serum sodium, 0.5 mmol/L per hour has been recommended for hypernatremic dehydration (219). With adequate rehydration alone (i.e., before commencing insulin therapy), serum glucose concentrations should decrease by 75–100 mg/dL (4.1–5.5 mmol/L) per hour (220, 221).
- A more rapid rate of decline in serum glucose concentration is typical during the first several hours of treatment when an expanded vascular volume leads to improved renal perfusion. If there is a continued rapid fall in serum glucose (>90 mg/dL, 5 mmol/L per hour) after the first few hours, consider adding 2.5 or 5% glucose to the rehydration fluid. Failure of the expected decrease of plasma glucose concentration should prompt reassessment and evaluation of renal function.
- Unlike treatment of DKA, replacement of urinary losses is recommended (120). The typical urine sodium concentration during an osmotic diuresis approximates 0.45% saline; however, when there is concern about the adequacy of circulatory volume, urinary losses may be replaced with a fluid containing a higher sodium concentration.

**Insulin therapy**

Whereas tissue hypoperfusion in HHS commonly causes lactic acidosis, ketosis is usually minimal. Early insulin administration is unnecessary in HHS. Fluid administration alone causes a marked decline in serum glucose concentration as a result of dilution, improved renal perfusion leading to glucosuria, and increased tissue glucose uptake with improved circulation. The osmotic pressure that glucose exerts within the vascular space contributes to the maintenance of blood volume. A rapid fall in serum glucose concentration and osmolality after insulin administration may lead to circulatory compromise and thrombosis unless fluid replacement is adequate. Patients with HHS also have extreme potassium deficits; a rapid insulin-induced shift of potassium to the intracellular space can trigger an arrhythmia.

- Insulin administration should be initiated when serum glucose concentration is no longer declining at a rate of at least 50 mg/dL (3 mmol/L) per hour with fluid administration alone.
In patients with more severe ketosis and acidosis, however, insulin administration should be initiated earlier.

Continuous administration of 0.025–0.05 units/kg/h can be used initially, with the dosage titrated to achieve a decrease in serum glucose concentration of 50–75 mg/dL (3–4 mmol/L) per hour.

- Insulin boluses are not recommended.

**Electrolytes**

In general, deficits of potassium, phosphate, and magnesium are greater in HHS than DKA.

- Potassium replacement (40 mmol/L of replacement fluid) should begin as soon as serum potassium concentration is within the normal range and adequate renal function has been established.
  - Higher rates of potassium administration may be necessary after starting an insulin infusion.
  - Serum potassium concentrations should be monitored every 2–3 h along with ECG monitoring.
  - Hourly potassium measurements may be necessary if the patient has hypokalemia.

- Bicarbonate therapy is contraindicated; it increases the risk of hypokalemia and may adversely affect tissue oxygen delivery.

- Severe hypophosphatemia may lead to rhabdomyolysis, hemolytic uremia, muscle weakness, and paralysis. Although administration of phosphate is associated with a risk of hypocalcemia, an IV solution that contains a 50:50 mixture of potassium phosphate and another suitable potassium salt (potassium chloride or potassium acetate) generally permits adequate phosphate replacement while avoiding clinically significant hypocalcemia.
  - Serum phosphate concentrations should be measured every 3–4 h.

- Patients with HHS frequently have large magnesium deficits, but there are no data to determine whether the replacement of magnesium is beneficial.
  - Replacement of magnesium should be considered in the occasional patient who experiences severe hypomagnesemia and hypocalcemia during therapy. The recommended dose is 25–50 mg/kg per dose for 3–4 doses given every 4–6 h with a maximum infusion rate of 150 mg/min and 2 g/h.

**Complications**

- Venous thrombosis associated with the use of central venous catheters is a common hazard in HHS (69). Prophylactic use of low-dose heparin has been
Diabetic ketoacidosis and hyperglycemic hyperosmolar state

suggested in adults but there are no data to indicate benefit from this practice. Heparin treatment should be reserved for children who require central venous catheters for physiologic monitoring or venous access and are immobile for more than 24–48 h (32). The central venous catheter should not be used for insulin administration because the large dead space may cause erratic insulin delivery.

- **Rhabdomyolysis** may occur in children with HHS resulting in acute kidney failure, severe hyperkalemia, hypocalcemia, and muscle swelling causing compartment syndrome (222). The classic symptom triad of rhabdomyolysis includes myalgia, weakness, and dark urine; monitoring creatine kinase concentrations every 2–3 h is recommended for early detection.

- For unknown reasons, several children with HHS have had clinical manifestations consistent with malignant hyperthermia, which is associated with a high mortality rate (26, 223–225). Patients who have a fever associated with a rise in creatine kinase concentrations may be treated with dantrolene, which reduces release of calcium from the sarcoplasmic reticulum and stabilizes calcium metabolism within muscle cells. Nonetheless, of the three reported patients with HHS reported to have been treated with dantrolene only one survived (223, 225).

- Altered mental status is common in adults whose serum osmolality exceeds 330 mOsm/kg; however, cerebral edema is rare (28). Among 96 cases of HHS reported in the literature as of 2010, including 32 deaths, there was only one instance of cerebral edema (Rosenbloom, personal communication). A decline in mental status after hyperosmolality has improved with treatment is unusual and should be promptly investigated.

**Mixed HHS and DKA**

Treatment must take into account potential complications of both DKA and HHS. Mental status must be closely monitored and frequent reassessment of circulatory status and fluid balance is necessary to guide therapy. To maintain an adequate circulatory volume, the rate of fluid and electrolyte administration usually exceeds that required for the typical case of DKA. Insulin is necessary to resolve ketosis and arrest hepatic gluconeogenesis; however, insulin infusion should be deferred until after the patient has received an initial fluid bolus and the circulation has been stabilized. Serum potassium and phosphate concentrations should be carefully monitored as described above for HHS.

**Prevention of recurrent DKA**

Management of an episode of DKA is not complete until its cause has been identified and an attempt made to treat it.

- Insulin omission, either inadvertently or deliberately, is the cause in most cases.
- The most common cause of DKA in insulin pump users is failure to take extra insulin with a pen or syringe when hyperglycemia and hyperketonemia or ketonuria occur.
- Home measurement of blood BOHB concentrations, when compared to urine ketone testing, decreases diabetes-related hospital visits (both emergency department visits and hospitalizations) by the early identification and treatment of ketosis (226). Blood BOHB measurements may be especially valuable to prevent DKA in patients who use a pump because interrupted insulin delivery rapidly leads to ketosis.
  - There may be dissociation between urine ketone (sodium nitroprusside only measures acetoacetate and acetone) and serum BOHB concentrations, which may be increased to levels consistent with DKA at a time when a urine ketone test is negative or shows only trace or small ketonuria (227).

- There usually is an important psychosocial reason for insulin omission.
  - An attempt to lose weight in an adolescent girl with an eating disorder.
  - A means of escaping an intolerable or abusive home situation.
  - Depression or other reason for inability of the patient to manage the diabetes unassisted.

- A psychiatric social worker or clinical psychologist should be consulted to identify the psychosocial reason(s) contributing to development of DKA.
- An infection is rarely the cause of DKA when the patient/family is properly educated in diabetes management and is receiving appropriate follow-up care by a diabetes team with a 24-h telephone helpline (228–230).
- Insulin omission can be prevented by comprehensive programs that provide education, psychosocial evaluation, and treatment combined with adult supervision of the entire process of insulin administration (231).
  - Parents and patients should learn how to recognize and treat ketosis and impending DKA with additional rapid- or short-acting insulin and oral fluids.
Families should have access to a 24-hour telephone helpline for emergency advice and treatment (228).

When a responsible adult administers insulin there may be as much as a 10-fold reduction in frequency of recurrent DKA (231).
