5.1 WOOD LIGHT-FRAME CONSTRUCTION

5.1.1 General Components

In residential construction, the walls provide the primary lateral resistance to wind and earthquake loads. Even in frame type houses (e.g., post-beam construction), the exterior walls provide most of the lateral stability to the house. Although this guide focuses on wood light-frame construction, alternatives such as cold-formed steel, masonry, and concrete construction are used in many regions of the country. The reader is referred to the sections on masonry and concrete construction later in this chapter for some guidance on the use of these materials. For cold-formed steel construction, the reader is referred to the American Iron and Steel Institute’s (AISI) industry standard for prescriptive cold-formed steel construction, Standard for Cold-formed Steel Framing Prescriptive Method for One- and Two-Family Dwellings (2001).

Light-frame walls provide resistance to sliding, overturning, and racking loads induced in the house by an earthquake as illustrated in Figure 5-1. The walls are the principle element for transmitting the loads from the upper stories and roof to the foundation. The concept of how these loads are transferred between the major components of the house is illustrated in Figure 5-2, and the action of the individual wall segments resisting the lateral loads is illustrated in Figure 5-3. Wood light-frame walls typically consist of the lumber framing covered by sheathing material that is attached to the wood framing with nails, staples, or screws. Figure 5-4 illustrates the components of a wall that is sheathed with wood structural panels (OSB or plywood) on the outside and gypsum wallboard on the inside. The figure also shows the addition of hold-down connectors to the framing, which are required by the IRC for some specific bracing configurations. When used, hold-down connectors increase the strength and stiffness of the wall segment.

Four different bracing wall configurations and eight methods (materials) are recognized by the IRC. The bracing wall configurations include:

- IRC Section R602.10.3 braced wall panels (Figure 5-5a),
- IRC Section R602.10.5 continuous (wood) structural panel sheathing (Figure 5-5b),
- IRC Section 602.10.6 alternate braced wall panels (similar to Figure 5-5c), and
- Wood structural panel sheathed walls with hold-down connections as required by the exceptions in IRC Section R703.7 when stone or masonry veneer is used (Figure 5-5c).
Figure 5-1 Sliding, overturning, and racking action resisted by walls and foundation.
Figure 5-2 Exploded view of house illustrating load paths.
Figure 5-3 Wall action for resisting lateral loads

Figure 5-4 Exploded view of typical residential wall segment.
Differences in these bracing wall configurations include sheathing materials, minimum bracing length, extent of sheathing, and anchorage at the wall base. Differences in overturning anchorage for walls are shown in Figure 5-5.

The braced wall panel (IRC Section R602.10.3) is the most commonly used approach. Eight different methods (materials) are recognized by the IRC as acceptable bracing. These are called “braced wall panel construction methods” in the IRC and are listed in Table 5-1. Method 1, let-in bracing, is not allowed to be used in regions of high earthquake hazard because it often will fail as the walls are racked during an earthquake; therefore, this method is not discussed further in this guide.

Of the acceptable braced wall panel materials, wood structural panels and diagonal lumber sheathing are known to perform better than others (i.e., withstand higher deformations while supporting higher loads). Wall panel bracing is required by IRC Section R602.10.4 to be provided in 4-foot minimum lengths sheathed on one face for other than Method 5 and either 4-foot lengths sheathed on both faces or 8-foot lengths sheathed on one face for Method 5. Other than with Method 5, this bracing often is provided in 4-foot-long isolated segments along the wall length.

Where braced wall panels use wood structural panel (Method 3) or diagonal lumber (Method 2) sheathing, the panel base anchorage to the supporting floor framing or foundation limits the bracing strength and stiffness. The braced wall panel anchorage includes two critical weak links for uplift: the panel end stud connection and the bottom plate (sole plate) connection. Braced wall panel bottom plates are specified by IRC Table R602.3(1) to be attached to the floor platform using three 16d common (0.162 x 3.5 inch) or 16d box (0.148 x 3.5 inch) nails every 16 inches or are specified by IRC Section R403.1.6 to be anchored to the foundation with 1/2-inch-diameter anchor bolts at not more than 6 feet on center. Together, these two weak links cause the wall to fail along the bottom of the wall under relatively low loads (these walls have a capacity of approximately 150 to 400 plf, which translates to an allowable design value of about 50 to 140 plf maximum).

IRC Section R602.10.5, continuous structural panel sheathing, requires that all exterior wall surfaces on a given story level other than door and window openings be sheathed with wood structural panel sheathing (Figure 5-5b). This bracing wall configuration has greater strength and stiffness than braced wall panels with minimum wall base anchorage. The increased strength and stiffness are due in part to the continuity provided by additional sheathing above and below windows and doors (which makes the wall-base connection capacity less critical) and increased overturning capacity due to required corner framing details or hold-downs at wall ends. In recognition of the improved strength and stiffness provided with continuous structural panel sheathing, IRC Section R602.10.5 permits the minimum length of bracing to be reduced and IRC Table R602.10.5 permits use of individual wall bracing panels that are more slender than would otherwise be permitted.

Wood structural panel wall bracing with uplift anchorage provided at each end, per IRC Sections R602.10.6 and R703.7, is the strongest and stiffest option for resisting lateral loads. This wall configuration is illustrated in Figure 5-5c. Although sheathing, fastening, and hold-down loads for these walls are prescribed, the walls are essentially equivalent to engineered shear walls. The alternate braced wall panel provisions of IRC Section R602.10.6 were developed to allow use of braced wall panels narrower than the 4-foot minimum required by IRC Section R602.10.4 (e.g., at the side of garage doors); however, the IRC permits an alternate braced panel to be substituted for each 4 feet of bracing throughout the house. The provisions of IRC Section R703.7 use
increased wall strength and stiffness to compensate for the increased earthquake loads that occur due to the weight of stone or masonry veneer. As discussed above, where wood structural panel bracing is used, the strength and stiffness of the wall bracing is very dependent on the extent of sheathing and anchorage at the wall base. The configuration shown in Figure 5-5a, using IRC minimum braced wall panel anchorage, is the weakest and least stiff of the wood structural panel bracing configurations. The configuration shown in Figure 5-5b adds strength and stiffness by providing continuous structural panel sheathing and added detailing or tie-downs at wall ends. The strongest and stiffest configuration is illustrated in Figure 5-5c where overturning anchors are provided at each end of each wall segment.

Above-code Recommendation: Use of the configurations shown in Figures 5-5b or 5-5c can significantly increase the strength and stiffness of braced wall panels sheathed with wood structural panel or diagonal lumber sheathing and may be used to provide improved performance whether or not specifically required by the IRC. Use with sheathing materials other than Methods 2 or 3 would provide less benefit and is not recommended.

When the wood structural panel wall bracing option is used in an engineered design, the walls are designed according to empirical tables that provide allowable design loads in pounds per foot of wall depending on the thickness and grade of the sheathing and the size and spacing of the sheathing nails. These walls rely on hold-down anchor connections to resist the overturning loads and substantial connections (nails, lag screws, bolts, etc.) along the top and bottom plates to transmit the lateral loads between the wall framing and the floor platform or foundation. This type of wall can resist allowable design loads up to 870 plf when sheathed on one face with wood structural panels.

5.1.2 Design Requirements

The 2003 IRC requires that wall bracing be provided both at exterior walls and at interior braced wall lines. IRC Section R602.10.1.1 specifies that interior braced wall lines must be added such that the distance between braced wall lines does not exceed 35 feet; however, allowance is made for spacing up to 50 feet. IRC Section R602.10.11 reduces the maximum spacing to 25 feet in SDCs D1 and D2. Within each braced wall line, IRC Table R602.10.1 specifies the minimum bracing as a percentage of the length of the wall line based on the wind and earthquake exposure and the story level under consideration (the lower in the house, the more sheathing is required to resist the higher loads). Some interpretations of the IRC would allow a house located in SDC C to be braced according to the amounts required for SDCs A and B due to the exemption for detached houses in SDC C from all earthquake requirements.

Above-code Recommendation: Houses in SDC C should be braced according to the requirements of SDC D1. Use of the required percentage of wall bracing in each 25-foot length of wall will provide a distributed resistance system of walls rather than a concentrated wall system. Experience has shown that a distributed wall system performs better in an earthquake than concentrated walls in only a few locations.
Table 5-2 excerpts a portion of this bracing information. As previously noted, the amount of bracing may be modified in accordance with *IRC* Section R602.10.5 when continuous wood structural panel sheathing is provided. In addition, an alternate braced wall panel (per *IRC* Section R602.10.6) can be substituted for each 4 feet of braced wall panel. The sheathing must be located at the ends of each braced wall line at least 25 feet on center. The idea is to provide a distributed resisting system rather than to concentrate the resistance in a few highly loaded wall segments. Overall, this provides a more robust structure that can resist the loads induced into the house close to the source of the load and not require the floor and roof diaphragms to transmit the loads long distances. Let-in bracing is allowed only for the top story of houses in SDC C due to its tendency to fail at relatively low lateral load levels.

Although the basic *IRC* bracing concept is reasonably straightforward, a number of other adjustments may modify the required length of bracing. Close attention is required to ensure that the *IRC* requirements are met. *IRC* Section R301.2.2.2.1 limits the dead load of assemblies for houses in SDCs D1 and D2. The maximum permitted for roof plus ceiling dead load is 15 psf (typical asphalt shingle roofs with gypsum ceilings); however, *IRC* Table R301.2.2.2.1 permits this assembly weight to be increased to 25 psf (for heavier roofing materials) provided that the length of wall bracing is increased as specified. Footnote d to *IRC* Table R602.10.1 notes that the earthquake bracing requirements are based on 15 psf (exterior) wall dead load and permits the required earthquake bracing length to be multiplied by 0.85 for walls with dead loads of 8 psf or
less, provided that the length is not less than required by IRC Section R602.10.4 (4 feet for all but let-in bracing and gypsum board, which require a length of 8 feet) nor less than required for wind loading.

In addition to the adjustments to required bracing length, the second paragraph of IRC Section R602.10.11 (errata, second printing) permits the wood structural panel wall sheathing to begin up to 8 feet from the corner in SDCs D₁ and D₂ provided that:

- A 2-foot braced panel is applied in each direction at the house corner or
- Tie-downs are provided at the end of the braced wall panel closest to the corner.

This is more stringent than for low SDCs where braced wall panels are permitted to be located up to 12 feet 6 inches from wall corners without providing tiedowns or sheathed corners and farther from corners if collectors are provided to carry loads to the braced wall panels. However, a house that is tied together at the corners will resist the loads expected from an earthquake much better than if the corners are not connected well. When using bracing other than wood structural panels in SDCs D₁ and D₂, braced wall panels must be located at each end of braced wall lines.

**Above-code Recommendation: Braced wall panels should extend to every corner.**

IRC Section R703.7 presents additional bracing modifications where exterior veneer is used. These requirements are discussed in Section 5.2 of this guide. For the guide’s model house, Figures 5-6a through 5-6c provide plan views identifying the bracing required when the house is in SDC C, has a light finish system such as vinyl siding, and has a crawl space. The bracing requirements for the same house located in SDC D₂ are shown in Figures 5-7a through 5-7c. Notice the significant increase in designated wall bracing due to the higher level loads expected in SDC D₂.

5.1.3 Cripple Walls

Cripple walls are short frame walls that extend from the foundation to the bottom of the first floor. They are most often found in the western United States. These walls often enclose a crawl space or serve as walls for a stepped foundation. Historically, these walls have been the cause of significant failures in residential construction during earthquakes primarily due to inadequate in-plane strength or inadequate anchorage to the foundation. These walls are the most highly loaded of all the light-frame walls in a house because they have to resist the entire load from the house above. For cripple walls, IRC Section R602.10.2.1 specifies the length of bracing as 1.15 times the bracing required for the story above and indicates that the spacing should be 18 feet instead of 25 feet. This is not applicable in SDC D2, however, where the IRC requires that the cripple wall bracing be a minimum of 75 percent of the wall length and be constructed using wood structural panels. When interior braced wall lines are not supported on a continuous foundation, cripple wall bracing lengths in SDCs D1 and D2 must be modified to increase the sheathing length by 50 percent at exterior braced wall lines or to decrease the nail spacing along sheathing edges to 4 inches on center (per IRC Section R602.10.11.1).

5.1.4 Quality Assurance

Quality assurance for the typical light-frame wall is really quite simple. There are essentially three areas to inspect:

- The sheathing nails,
- The anchorage of the framing to the floor framing or foundation below, and
- The anchorage of the wall framing to the roof or floor framing above.

The most common problem that adversely affects the performance of all wall types is the overdriving of the nails attaching the sheathing to the studs; this is especially a problem when pneumatic or power-driven nail guns are used. All of the nails used to attach the sheathing to the wall framing should be driven only to where the nail head is flush with the surface of the sheathing as shown in Figure 5-8; an improperly driven (overdriven) nail also is shown in Figure 5-8.

![Figure 5-8 Properly and overdriven nails.](image)
The most important nails are those around the perimeter of each panel of sheathing. These nails govern the strength and stiffness of the panel. If the nails are overdriven (as in Figure 5-8), the strength of the connection is severely compromised. For instance, if 3/8-inch wood structural panel sheathing is used and the nails are overdriven 1/8 inch (typical for many pneumatic nail tools), the strength of the wall is reduced as much as 40 to 50 percent. It is therefore imperative that the sheathing nails be inspected to ensure that they are properly driven. Many pneumatic nail tools have default driving pins that overdrive the nails but changing the driving pin costs little (less than 10 percent of the original cost of the tool). Many tool manufacturers now provide an adjustment on the tool to allow the user to change the depth of the driving pin without replacing the part. (It is recommended that where nail heads occasionally are more than 1/16-inch below the surface, an additional nail should be provided between existing nails. If a substantial number of nails are overdriven, the sheathing should be removed and the framing checked for splitting before replacing the sheathing with proper nailing.)

Nails often are located too close to the edge of the sheathing panel, which can result in the nails tearing out the side of the panel and weakening the wall. Therefore, the minimum edge distance for nailing sheathing is 3/8 inch. The larger the edge distance is, the stronger the wall will be. This is especially true for the row of nails at the bottom of the wall. If the bottom row of nails is located at the mid-height of the bottom plate for the wall, the displacement capacity of the wall is almost double that when the nails are spaced at 3/8 inch. When the edges of two sheathing panels meet on a common stud (2x nominal), the maximum edge distance should be 3/8 inch to prevent the nail from splitting the edge of the stud behind the sheathing.

Another common problem is that the nails are driven through the sheathing but miss the stud behind. Although it is obvious that nails in the air provide no strength or stiffness, this problem is so common it merits emphasizing that sheathing nails must be driven into the studs and top and bottom plates of the wall and not miss the framing. The use of pneumatic nail guns makes it very difficult for the operator to “feel” whether or not the nail has been driven into the stud behind; therefore, all such nailing must be visually inspected from behind to ensure that the nails did not miss the studs.

Finally, the sheathing nailing around the perimeter of each sheet of sheathing should be symmetric about the center of the sheathing panel. This means that there should be approximately the same number of nails along each parallel side of the panel as illustrated in Figure 5-9.

The second area to inspect for quality assurance is the anchorage at the bottom of the wall. For prescriptive walls, the nails must pass through the bottom plate into the floor framing. If the nails miss the floor joists, they have no capacity to resist withdrawal and sliding. If the wall is attached directly to the foundation, 1/2-inch-diameter anchor bolts should be spaced at a maximum of 6 feet on center, and the end bolts should be not more than 12 inches nor closer than 7 bolt diameters from the end of the plate. If the house is located in SDC D1 or D2, the anchor bolts are required to have a steel plate washer between the wood sill plate and the nut. (See Section 3.10 of this guide for more discussion of the use of plate washers.) If the walls are segmented (engineered), the hold-down connector needs to be attached to the end stud (usually a
double stud) and the bolt or threaded rod holding the connector to the foundation or story below needs to be tightened to a snug one-quarter turn condition. Tightening the nut more does not provide higher reliability due to the fact that wood is viscoelastic and the tension in the bolt will not be sustained over time. A common practice to prevent the nuts from loosening during an earthquake is to use a double nut or slack take-up device. The hold-down should connect the end stud either directly to the foundation or to the top of a stud in a wall of the story below in order to effectively transmit the overturning loads into an active resisting element.

Finally, the connection between the top plate and the roof framing or floor framing for the story above should be checked. The lateral loads are transmitted through nails or other fasteners connecting the top plate of the wall to the floor or ceiling joists above. (For vaulted ceilings, the connection might be between the top plate and the rafters.) If there is a wall on the story above that has an overturning anchor attached to the end stud, there should be an equivalent connection near the top of a stud in the story below that is upside down from the one on the wall above. A threaded rod should connect the two hold-down anchors to transmit the loads between them. If a stud is being used to transmit overturning loads from the story above, it will need to have an overturning anchor at its base to transmit the loads to the next story or foundation below.
Above-code Recommendations: Improving the detailing of the braced wall system is the most effective way to obtain earthquake performance levels higher than the code minimums. It is also most effective to concentrate on the lower stories of the house since this is the area that typically has the fewest walls and experiences the highest loads during an earthquake.

Use of continuous structural panel sheathing is recommended as an above-code measure (see Section 5.1.1 and Figure 5-5b of this guide). The analyses of the model house used in this guide indicated that use of continuous wood structural panel sheathing with overturning anchors at corners significantly reduced the drift in all SDCs and improved the performance category from “significant damage” to “moderate damage” in SDC D2. The cost of making this change would be approximately 9 to 10 percent of the cost of the structural portion of the model house. The percentage of the total cost of the house would depend on the level of finishes, fixtures, windows, etc., and the cost of the land relative to the cost of the structural portion of the house. The structural portion of house costs ranges from 15 to 25 percent of total cost; therefore, the cost of fully sheathing a typical house would be approximately 1.5 to 2.5 percent of its total cost.

Use of wood structural panel sheathing extending over and nailed to the floor rim joist or blocking is recommended as an above-code measure. This is illustrated in Figure 5-10 and can be accomplished either by sheathing the wall with oversized panels (9-foot panels on an 8-foot wall) or by cutting and blocking standard size sheets. It is important to leave a vertical gap between sheathing panels at the mid-height of the band joist (approximately 3/4 inch for green solid sawn floor framing) to allow for shrinkage of the wood floor member without causing the sheathing to buckle. Analytical studies of the model house used in this guide indicated that use of sheathing spliced on the rim joist increased the approximate performance category from “significant damage” to “moderate damage” in SDC D2. Improvements identified in the analytical study were less significant in SDCs C and D1. For the model house, the cost of implementing this improvement would be approximately 0.5 percent of the cost of the structural portion of the house, essentially a no-cost item when the total cost of the house is considered.

Use of hold-down anchors at each end of each wood structural panel wall segment is recommended as an above-code measure (see Section 5.1.1 and Figure 5-5c of this guide). Analytical studies of the model house used in this guide indicated that the addition of hold-down anchors significantly reduced drift in all SDCs and the approximate performance category was increased from “significant damage” to “moderate damage” in SDC D2. For the model house, the cost of this improvement would be 18 percent of the structural cost of the house or 2.5 to 4.5 percent of its total cost. This option provides a house with the best connectivity and is the basis for engineered shear wall construction. Further, of all the options, it has the greatest effect on the stiffness and strength of the wall.
Above-code Recommendation: Although not addressed in the analytical studies, use of the above-code measures in combination is thought to have a cumulative effect and is **recommended**. This level of connectivity will further improve earthquake performance by stiffening and strengthening the walls. **Additional above-code options for increasing strength and stiffness** include spacing sheathing nails closer than the standard 6 inches on center (additional detailing requirements may be applicable at 3-inch or closer spacing; see the *IBC*) and placing wood structural panel sheathing on both faces of walls. Use of these **above-code** recommendations will be most effective where the highest loads are present, such as lower stories and cripple wall levels.

![Sheathing Detail](image)

**Figure 5-10** Sheathing detail for extending the sheathing over the band joist.
5.2 STONE AND MASONRY VENEER

Masonry and stone veneer are popular exterior finish materials for residential construction (Figure 5-11). Veneer provides a durable finish for the house but, unfortunately, the added weight of these veneers increases the loads experienced during an earthquake. The IRC permits use of stone and masonry veneer installed over concrete or masonry walls and over a backing of wood light-frame or cold-formed steel construction.

![Applications of masonry and stone veneer](image)

**Figure 5-11** Applications of masonry and stone veneer.

This guide section discusses general principles of earthquake-resistant design for houses with veneer, specific IRC requirements important to earthquake performance, and above-code measures for improved earthquake performance.

Stone and masonry veneer is addressed in IRC Sections R702.1 (interior) and R703.7 (general and exterior). For earthquake-resistant construction using veneer, there are two major areas of concern:

- The increased earthquake loading on the house due to the weight of the veneer and
- Adequate anchorage of the veneer.

The weight of stone and masonry veneer permitted under the IRC provisions can vary from as little as 20 pounds per square foot installed for adhered veneer to as much as 70 psf installed for a 5-inch-thick anchored veneer with 1 inch of grout. The weight of stone and masonry veneer greatly increases the overall weight of a light-frame house and, as a result, the earthquake loads. The IRC provisions rely exclusively on the strength and stiffness of the light-frame bracing systems to resist wind and earthquake loads, discounting any strength and stiffness that might be provided by the veneer. This is primarily because there is only limited understanding of the ability of the veneer to resist cyclic earthquake loading while acting in combination with the light-frame bracing systems and because the veneer cracks and breaks at smaller displacements than required for the light-frame system to achieve its capacity. As a result, additional requirements apply to light-frame systems with veneer in areas with higher earthquake risk.
Masonry and stone veneers have been damaged in historic earthquakes. Figure 5-12 illustrates damage that occurred during the Northridge earthquake that appears to be due to inadequate connection of the wall studs to the top and bottom plates. In failing, the stone veneer pulled the wall sheathing and many of the studs out of the wall perpendicular to the pictured wall.

Figure 5-12  Stone veneer damaged during the earthquake in Northridge, California.

5.2.1  *IRC* Earthquake Requirements

The *IRC* permits use of veneer above the first story above grade in SDCs D₁ and D₂ only for one- and two-family detached houses of wood light-frame construction without cripple walls.

If a house does not meet these requirements, a design professional should design the house following the requirements of the *International Building Code* or *NFPA 5000*. For veneer installed over a light-frame system, requirements are incrementally more restrictive for higher SDCs (*IRC* Section R703.7). References to the veneer provisions for SDCs C, D₁, and D₂ appear in *IRC* Sections R301.2.2.3.1 and R301.2.2.4.2.

For light-frame systems, the general rule is that stone and masonry veneer not exceeding 5 inches in thickness is permitted in the first story above grade across all SDCs without any further requirements (*IRC* Section R703.7).

Although this veneer will have some impact on earthquake performance, the increase in earthquake load close to the house base is not judged to have significant life-safety implications.

In SDCs A and B, veneer on wood light-frame or cold-formed steel houses can be up to 5 inches thick and extend up to 30 feet above a noncombustible foundation with an additional 8 feet permitted for gable end walls. The 30-foot limit corresponds to the height at which additional
vertical support of the veneer would be required in an engineered design. Veneer in SDCs A and B has no imposed earthquake limitations, leaving wind provisions to control.

In SDC C, veneer on wood light-frame or cold-formed steel houses can be up to 5 inches thick and extend up to 30 feet above a noncombustible foundation with an additional 8 feet permitted for gable end walls. It is required, however, that the length of bracing walls in other than the topmost story be 1.5 times the length required if veneer is not used. (Note that this provision is applicable to all houses in SDC C.)

In SDC D₁, wood light-frame houses are permitted to have veneer up to 4 inches in thickness for a height of 20 feet above a noncombustible foundation with an additional 8 feet allowed for gable end walls or up to 30 feet where the bottom 10 feet (first story) is anchored to a concrete or masonry wall. However, IRC Section R301.2.2.2.1 assembly weight limits for concrete and masonry leave little allowance for veneer weight. Where assembly weight limits cannot be met, engineered design of the concrete or masonry walls may be required.

Veneer on wood light-frame walls in SDC D₁ (see IRC Section R703.7) is dependent on the use of wood structural panel sheathing with specified nail size and spacing, increased bracing lengths, use of hold-downs with specified capacities at each end of each braced wall panel, and the prohibition of cripple walls as previously mentioned. The minimum sheathing must be at least 7/16 inch thick and it must be fastened with at least 0.131 x 2.5 inch (8d common) nails that are spaced no more than 4 inches on center at the panel edges. The braced wall length for the top story of the house must be at least 45 percent of the total wall length. Finally, the first two stories must have hold-down connectors installed. The hold-down connectors for the transfer of loads from the second to the first story must have a minimum capacity of 2100 lb and from the first floor to foundation must have a minimum capacity of 3700 lb. Load path requirements with hold-down devices are discussed in Chapter 2 of this guide.

In SDC D₂, veneer provisions are similar to those for SDC D₁, except for a couple of small changes:

- The maximum thickness of the veneer is limited to 3 inches,
- The top story must be sheathed to 55 percent of the total wall length,
- The second-to-first story overturning anchors must have a capacity of 2300 lb, and
- The first-story-to-foundation overturning anchors must have a minimum capacity of 3900 lb.

Anchorage requirements for anchored stone or masonry veneer are given in IRC Section R703.7.4. Use of galvanized corrugated sheet metal ties or metal strand wire ties is required. The minimum gage required is No. 9 U.S. gage wire for strand wire ties and No. 22 U.S. gage by 7/8 inch corrugated sheet metal ties. The maximum supported veneer area is 2-2/3 square feet per tie for SDCs A, B, and C. The supported area is reduced to 2 square feet per tie for houses in SDC D₁ and D₂.
The intent of using ties for masonry veneer is not to prevent the veneer from cracking but rather to prevent the veneer from pulling away from the supporting wall system. In earthquakes, the desire is to prevent damaged veneer from becoming a falling hazard and the use of ties should accomplish this by holding the cracked veneer to the supporting wall.

**Above-code Recommendations:** The sheet metal ties or wires used to fasten veneers should be corrosion resistant, should penetrate the house paper and sheathing, and should be embedded into the wall studs. Fasteners that do not penetrate the studs (i.e., only the sheathing is penetrated) have low withdrawal resistance and significantly reduce the tie’s ability to hold the veneer to the wall.

Where veneer is limited to the first story above grade, increase the length of wood structural panel bracing and use hold-down devices on the braced wall panels in the first story to increase both the strength and stiffness of the first story above grade. These measures will help make the deformation behavior of the light-frame system more compatible with the veneer and reduce cracking of the veneer.

### 5.2.2 Quality Control

All mortar joints should be completely filled and well tooled for water tightness. This can have a significant effect on the strength and durability of the masonry walls and veneers. To augment the tooling of joints for improving moisture control (which directly affects the longer-term strength of the wall), flashing and weep holes need to be placed at the bottom of the veneer so that any water trapped between the veneer and the structural wall behind can be directed to the outside of the house. The flashing and weep holes frequently are omitted in residential construction, resulting in expensive repairs to the structural walls of the house.

Veneer should be placed such that a 1-inch cavity is maintained between the veneer and the supporting wall. This cavity provides a drainage plane for channeling the moisture that will migrate from the outside surface of the veneer to the inside and then to the bottom of the wall where it can escape to the outside through the weep holes. This drainage plane is very important to prevent the wall sheathing from being constantly wet, which will result in mold, mildew, and decay.

Anchor ties that hold the veneer to the wall need to be placed at the proper spacing to ensure that the area of veneer attributed to each tie does not exceed the maximum allowed for the particular Seismic Design Category. For SDCs D1 and D2, the spacing should be such that each tie is supporting no more than 2 square feet of veneer. The ties also need to be placed such that the nail holding the tie to the wall is embedded into a stud and not just the sheathing material.

Finally, if horizontal reinforcing wire is used, it should be a minimum size of W1.7 and should be placed at a maximum vertical spacing of 18 inches according to the 2002 *Masonry Standards Joint Committee Code* (ACI 530/ASCE 5/TMS 402, Section 6.2.2.10.2.4.). This wire is embedded in the horizontal mortar joints between the courses of brick. The brick ties that hold
the veneer onto the wall behind it should be bent around the wire to improve the effectiveness of the tie in preventing the veneer from falling off the wall during an earthquake.

5.3 COLD-FORMED STEEL HOUSES

The IRC permits cold-formed steel framing prescriptive construction. This guide section discusses the general principles of earthquake-resistant design for cold-formed steel houses, specific IRC requirements important to earthquake performance, and above-code measures for improved earthquake performance.

Cold-formed steel construction is, in most respects, like wood light-frame construction. The IRC contains provisions similar to the wood light-frame provisions for cold-formed steel floors, roofs, and walls. The weights of cold-formed steel floor, roof, and wall assemblies are the same or slightly lower than those with wood light-frame construction and result in very similar earthquake loads. The system resisting wind and earthquake loads most commonly consists of floor and roof assemblies acting as horizontal beams carrying loads to shear walls. Cold-formed steel shear walls carry wind and earthquake loads to the foundation. The IRC provides extensive illustrations of minimum construction requirements for cold-formed steel framing. One significant difference between steel and wood light-frame construction is that steel construction assumes that the framing is in-line – that is, that the rafters, studs, and floor joists line up so that the top channels of the walls and other elements are not subjected to compression and bending loads. Figure 5-13 shows a cold-formed steel house under construction.

Figure 5-13 Cold-formed steel house under construction.

5.3.1 Scope Limitations

The IRC limits the scope of cold-formed steel houses permitted under the prescriptive provisions. Some scope limitations are found in IRC Chapter 3 while others are found in IRC Section R603.

For all SDCs, steel light-frame houses are limited to two stories above grade; the maximum permitted plan dimensions are 60 feet perpendicular to truss or joist span and 36 feet parallel to truss or joist span (IRC Sections R505.1.1, R603.1.1, R804.1.1). For all SDCs, story height is limited to a 10 foot stud clear height plus a height of floor framing not to exceed 16 inches (IRC Section R301.3). For houses in SDCs D₁ and D₂, IRC Section R301.2.2.2.1 limits cold-formed steel wall assembly weights to 14 psf for exterior walls and 5 psf for interior walls. Floor and roof plus ceiling assembly weights are also limited to 15 psf by IRC Section R301.2.2.2.1.

Although some interpretations of the IRC assume the code does not directly require that the irregularity limits of IRC Section R301.2.2.2.2 be followed, the same limits are imposed by AISI’s Standard for Cold-formed Steel Framing – Prescriptive Method for One- and Two-Family Dwellings (2001) for SDCs D₁ and D₂. Attention to the issues associated with irregularities is important to prevent torsional response overloading of critical elements in the wall.

As for wood houses, the design of cold-formed steel houses is typically controlled by wind rather than earthquake loading through SDC C; as a result, there are no added IRC earthquake load requirements for SDC C. Per IRC Section R301.2.2.4.5, houses in SDCs D₁ and D₂ must conform to the requirements of the 2001 AISI Standard for Cold-Formed Steel Framing – Prescriptive Method for One- and Two-Family Dwellings (AISI/COFS/PM).

5.3.2 IRC Wind and Earthquake Requirements

Unlike wood light-frame systems, the cold-formed steel provisions rely exclusively on bracing at exterior walls for wind and earthquake load resistance. IRC Section R603.7 requires that the exterior walls be fully sheathed. IRC Table R603.7 specifies minimum percentages of full-height sheathing as a function of wind speed and exposure, roof slope, and story being braced. Per IRC Section R603.7, the minimum braced length is not permitted to be less than 20 percent of braced wall length and bracing panels must be a minimum of 4 feet in length to be counted towards the required percent with a minimum 4-foot-long bracing panel required at each corner of each exterior wall. The minimum wood structural panel sheathing thickness is specified as 7/16 inch for oriented strand board and 15/32 inch for plywood. The minimum edge fastening is spaced 6 inches on center using No. 8 screws. All wood structural panel edges are to be blocked.

A number of modifying factors are required to be applied to the tabulated percentage of full-height sheathing. The tabulated bracing percentages are based on walls with an 8-foot clear height and must be multiplied by 1.10 for a 9-foot clear height and 1.20 for a 10-foot clear height (IRC Section R603.7). The required sheathing percentage is permitted to be multiplied by 0.6 where hold-down devices having 4,300 lb capacity are provided at each end of each exterior wall (IRC Section R603.7.2). The minimum percentages of sheathing are based on a house aspect ratio (ratio of greater plan dimension to lesser plan dimension) of 1:1. The minimum
percentages for the shorter walls must be multiplied by 1.5 and 2.0 for house aspect ratios of 1.5:1 and 2:1 respectively (IRC Table R603.7, footnote c). The minimum percentages are permitted to be multiplied by 0.95 or 0.90 for hipped roofs, depending on roof slope (IRC Table R603.7, Footnote d).

AISI/COFS/PM provisions for bracing in SDCs D1 and D2 are significantly different from IRC requirements for areas of less earthquake risk with respect to bracing approach, percentage of full-height sheathing, and detailing. The IRC basic bracing provisions (SDCs A, B, and C) do not require use of hold-downs and permit reduction of the percentage of full-height sheathing if hold-downs are provided. In contrast, AISI/COFS/PM basic bracing provisions for SDCs D1 and D2 require use of hold-downs at each end of each required full-height sheathing segment. An alternative approach allows hold-downs to only occur at each end of a braced wall line provided that the length of full-height sheathing is increased (up to 3x length otherwise required). This alternative approach is similar to the continuous structural panel sheathing (perforated shear wall) method used in wood light-frame construction. The user is referred to the AISI/COFS/PM document for full details of bracing requirements.

IRC Section R505 addresses floor construction using cold-formed steel framing. The use of wood structural panel floor sheathing is implied by details and fastening requirements. IRC Section R503 controls selection of floor sheathing depending on the spacing of joists and material used. IRC Table R505.3.1(2) requires a minimum fastening of No. 8 screws at 6 inches on center on the perimeter of the sheathing panels and 10 inches on center in the field. This is assumed to be at supported edges with no requirements for blocking at other edges. Similarly, IRC Section R804 implies wood structural panel roof framing, while IRC Table R804.3 requires minimum No. 8 screws at 6 inches on center at edges, 12 inches on center in the field, and 6 inches on center at gable end trusses.

It is very important to use appropriate framing materials and fasteners for the performance of the wall bracing and floor and roof systems to be acceptable. IRC Sections R505.2, R603.2, and R804.2 specify material grade, corrosion protection, and identification of the materials required. IRC Sections R505.2.4, R603.2.4, and R804.2.4 specify fastener requirements. Steel to steel and wood structural panel sheathing to steel connections are required to be made with self-drilling tapping screws conforming to SAE J78 with a Type II coating in accordance with ASTM B633. Screws are required to extend through the steel a minimum of three exposed threads. Steel to steel connections are to be made with self-drilling tapping screws at a minimum edge and center-to-center distances of 0.5 inches. Connections are typically specified with No. 8 screws, but adjustments are given for use of No. 10 and No. 12 screws. Wood structural panel sheathing to steel framing connections are to be made with No. 8 self-drilling tapping screws at minimum head diameter of 0.292 inches, countersunk heads, and a minimum edge distance of 3/8-inches. Gypsum wallboard ceilings are to be attached with minimum No. 6 screws conforming to ASTM C 954.
5.3.3 Quality Control

Quality control for cold-formed steel construction can play a major role in the satisfactory performance of the house. Important steps in steel construction include ensuring proper load path connections. Just as in wood light-frame construction, the connections between the end studs and the floor or foundation become critical for the strength and stiffness to be the highest possible. Strong connections ensure the load path will function properly.

Adequate lateral bracing of all floor, roof, and wall framing members is important to prevent the individual members (joists or studs) from buckling. Cold-formed members have to be braced well before they can support significant compression loads. Attaching sheathing to the stud or joist typically will provide this lateral support.

Screws that attach the sheathing to the framing should be inspected to ensure that they are not overdriven (the resulting loss in capacity will be similar to that experienced in wood light-frame construction when nails are overdriven). Just as in wood framing, the power tools used to install the screws can easily over drill the screws, leaving the head of the screw below the surface of the sheathing material and significantly increasing the chances of pull through.

5.4 MASONRY WALL HOUSES

While many houses use masonry walls for foundations, some houses are built using masonry for the walls above grade. Figure 5-14 shows a house constructed using masonry for the walls. The IRC permits construction of houses with masonry walls in accordance with prescriptive provisions for concrete, brick, and stone masonry. General provisions for masonry construction appear in IRC Section R606. Additional details of construction for concrete unit masonry, brick masonry, and masonry grouting appear in IRC Sections R607 through R609. However, it is
important that all masonry cells with reinforcement be grouted, and care should be taken to ensure that the grout is consolidated. Discussed below are the general principles of earthquake-resistant design for masonry wall houses, specific IRC requirements important to earthquake performance, and above-code measures for improved earthquake performance.

Figure 5-14 House constructed with masonry walls.

Masonry wall construction is significantly heavier than light-frame wall construction; however, in most respects, the same principles of earthquake-resistant construction apply. The system resisting wind and earthquake loads most commonly consists of floor and roof assemblies acting as horizontal beams carrying loads to bracing walls. Masonry bracing walls carry wind and earthquake loads down to the foundation with masonry walls primarily resisting loads acting in their strong direction – that is, parallel to the wall. Because masonry walls are heavier than stud framing, it follows that the earthquake loads resisted by each wall element and connection will be greater. As a result, the design of the connections is as important as the proportioning of the floor and roof systems and bracing walls. Significant earthquake loads also develop perpendicular to the wall surface due to the wall’s weight. These loads tend to pull the walls away or push them toward the floor or roof, making wall to floor or roof anchorage critical. Damage from insufficient anchorage or connectivity similar to that shown in Figure 5-12 can result if these connections are not strong enough.

5.4.1 Scope Limitations

One of the primary approaches the IRC uses to deal with the increased earthquake loading associated with masonry wall houses is to limit the scope of houses permitted under the prescriptive provisions. IRC Section R301.2.2 introduces earthquake provisions applicable to houses in SDCs D₁ and D₂. The first scope limitation is found in IRC Section R301.2.2.2.1, Weights of Materials, which limits masonry walls to 8 inches thick and 80 pounds per square foot, which essentially prohibits the use of rubble stone masonry (IRC Section R606.2.2) as well as relatively thick concrete or brick masonry walls. IRC Section R301.2.2.4.3 triggers the reinforcement and configuration requirements of IRC Section R606.11.3 for all houses in SDC D₁ and of Section R606.11.4 for all houses in SDC D₂. In SDCs D₁ and D₂, the scope of
prescriptive construction of houses with masonry walls is effectively limited to walls one story in
height with up to 9 feet between lateral supports; beyond this, engineered design is required. A
final scope limitation in IRC Section R301.3, Item 3, limits masonry house walls to a clear height
of 12 feet with a maximum floor framing depth of 16 inches. An additional 8 feet of masonry
wall height is permitted for gable end walls. It is also worth noting that IRC Section
R301.2.2.2.2, Item 7, prohibits the mixing of light-frame and masonry construction such that
light-frame walls would be required to support earthquake loads due to masonry wall
construction (e.g., mixing masonry and light-frame walls on the same story.)

5.4.2 Wall Lateral Support, Reinforcing, and Anchorage

General requirements for lateral support of masonry walls for all SDCs are provided in IRC
Section R606.8. Walls are permitted to be laterally supported by cross-walls, pilasters,
buttresses, or structural frame members where walls span horizontally between supports and by
floors and roofs where walls span vertically between supports. Minimum reinforcing
requirements apply only for masonry laid in stack rather than running bond and for interior non-
load bearing walls where they intersect with other masonry walls. IRC Section R606.10 requires
anchorage of masonry walls to floor and roof systems in accordance with specific details.
However, in recent U.S. earthquakes, similar details have been observed to be susceptible to
damage. Performance of some of these details for supporting site-built masonry walls also is
thought to be problematic. Several details on how to comply with the IRC provisions are
provided in the code itself.

IRC Section R606.11.1.1 triggers additional requirements for floor and roof systems for houses
in SDCs D1 and D2. Floor and roof wood structural panel sheathing is required to have all edges
blocked and nailed at 6 inches on center. Where the floor or roof system is long and narrow
(more than twice as long as it is wide), the nailing at sheathing edges is required to be reduced
from 6 to 4 inches on center.

For houses in SDC D1, IRC Section R606.11.3 places further limits on masonry walls using
prescriptive provisions:

- Masonry walls are limited to one-story,
- Additional reinforcing is required,
- Reinforcement detailing provisions for masonry columns apply, and
- Type N mortar and masonry cement are prohibited.

Similar additional requirements are triggered by IRC Section R606.11.4 for SDC D2. SDCs D1
and D2 requirements are illustrated in IRC Figure R606.10(3). Again, specific design is required
for wall to framing anchorage per IRC Section R606.11.2.2.1; thus, the anchorage to roof
framing illustrated in IRC Figure R606.10(3) may not be the only alternative.

In the design of wall anchorage to the floor and roof, it is important that a direct tension tie be
provided from the wall to the floor or roof framing members if framing is perpendicular or to
blocking that is continued across the floor or roof if framing is parallel. Detailing in IRC Figures
611.8(1) to (7) shows the concept of this connection when used with concrete walls, but they are equally applicable to masonry construction.

### 5.4.3 Parapet walls

*IRC* Section R606.2.4 limits masonry thickness and height of parapets in all SDCs and sets the requirements for reinforcing walls of houses in SDCs D1 and D2. Parapet walls are easily damaged in an earthquake and attention to placement of reinforcement and bracing to stabilize the parapet is important.

### 5.4.4 Problematic Gaps Between Prescriptive and Engineered Construction

The current *IRC* requirements for masonry construction reveal significant gaps between prescriptive and engineered construction, creating a significant opportunity to employ *above-code* measures to improve performance.

For areas of high earthquake risk, one notable omission is the lack of a limit on the amount of opening in masonry walls. Light-frame provisions require a percentage of the wall to be solid to provide bracing so that the bracing wall strength is in proportion to the earthquake load, but the same requirement is not imposed for masonry walls. This is of particular concern when the house layout results in front and back walls with a large percentage of openings for doors and windows.

**Above-code Recommendation:** Each exterior wall and each interior bracing wall should have at least one, and preferably two, sections of solid wall not less than 4 feet in length. Further, sections of solid wall should not be spaced more than 40 feet on center and should be placed as symmetrically as possible (Figure 5-15). The provisions of *IRC* Section R611.7.4 for ICF walls illustrate a reasonable approach to regulation of minimum wall length. The improvement requires only reasonable planning and should not result in higher construction costs.

*IRC* Section R403.1 requires that exterior walls be supported on continuous concrete or masonry footings and regulates minimum footing width and depth, but nothing in the *IRC* appears to require that other masonry walls be supported on foundations.

**Above-code Recommendation:** It is vital that all masonry walls be supported on substantial continuous footings extended to a depth that provides competent bearing. If this is not done the walls have a high probability of being damaged due to uneven settlement.

There are no *IRC* maximum spacing limitations between lines of masonry bracing walls corresponding to the light-frame limits of 25 and 35 feet. In light-frame construction, these spacing limitations are intended to help distribute the bracing walls in proportion to the house mass (dead load) as well as to limit the loading to the floor and roof, which helps prevent damage to the house from rotation due to torsional irregularities caused by irregular floor and roof system shapes.
Above-code Recommendation: Solid portions of wall should be stacked from floor to floor and masonry walls should be continuous from the top of the structure to the foundation. Masonry walls not directly supported on walls below require engineered design for gravity load support. Design for earthquake and wind loads also should be provided. The cost of this improvement is negligible; it requires only proper planning when laying out the wall positions for the house.

The IRC also does not regulate house irregularities for masonry construction. The concepts behind IRC Section R301.2.2.2.2, Irregularities 1 through 6, should apply equally to a masonry wall house. The exceptions to Irregularities 2 and 5 also can be applied; however, the rest of the exceptions are not applicable.

Above-code Recommendation: Because prescriptive detailing is not available for the addition of interior masonry braced wall lines, it is recommended that the distribution of bracing walls be carefully balanced and that the floor and roof plans use simple rectangular shapes without indentions, bump-outs, or openings. The cost associated with this improvement is proportional to the length of wall added in relation to the initial total wall length.
5.4.5 Quality Control

Quality control during masonry construction can play a major role in the satisfactory performance of the masonry. The following should be monitored:

- Proper placement of reinforcing in masonry. Unless specifically designed otherwise, reinforcing should be located as near the centerline of the masonry cavity as possible. In no case should reinforcing be closer than 5/8 inch to a masonry unit wall.

- Anchor bolts should be secured into place before grout placement (not placed into grout following the pour).

- Excess mortar and other obstructions should be cleaned from the cavity to allow free placement of grout.

- Consolidation of the grout after it is placed into the cavity is necessary to eliminate voids.

5.5 INSULATING CONCRETE FORM (ICF) WALL HOUSES

The IRC permits construction of houses with concrete walls in accordance with the prescriptive provisions of IRC Section R611 for ICF (insulating concrete form) walls and Section R612 for conventionally formed walls. ICF walls are concrete that is cast into forms that remain in place to serve as house insulation. The code covers three geometries of ICF forms: flat, waffle-grid, and screen grid forms. Both the waffle and screen grid consist of concrete cast into a series of interconnected horizontal and vertical cores within the insulation. Interior and exterior wall
finishes are applied over the ICF wall form. ICF walls may be used for the full height of the house or for the lower story only with light-frame walls above. The provisions of IRC Section R611 are based on the use of light-frame floor, roof, and ceiling assemblies in ICF wall houses. The light-frame construction can be either wood or steel light-frame; however, current detailing developed for areas of high earthquake demand provides solutions for wood light-frame floors and roofs. This section discusses general principles of earthquake-resistant design for ICF wall houses, specific IRC requirements important to earthquake performance, and above-code measures for improved earthquake performance. An example of ICF construction is shown in Figure 5-16.

Figure 5-16 Insulated concrete form house under construction.

ICF wall construction, like masonry, is significantly heavier than light-frame wall construction. In most respects, however, the same principles of earthquake-resistant construction apply. The system resisting wind and earthquake loads consists of floor and roof assemblies acting as horizontal beams carrying loads to bracing walls. ICF bracing walls carry wind and earthquake loads down to the foundation with ICF walls primarily resisting loads acting in their strong direction, parallel to the wall (shear walls). Because ICF walls are heavier than light-frame walls, the earthquake loads to be resisted by each wall element and connection will be greater. As a result, proportioning of the floor and roof systems and bracing walls is important as are the connections between the walls and the floor and roof framing. Significant earthquake loads also develop perpendicular to the wall surface due to the wall weight. These loads tend to pull the walls away or push them toward the floor or roof, making wall to floor and wall to roof anchorage very important.

5.5.1 Scope Limitations

One of the primary approaches the IRC uses to address the increased earthquake loading with ICF wall houses is to limit the scope of houses permitted under the prescriptive provisions. For ICF, some scope limitations are found in Chapter 3 while others are found in IRC Section R611. For all Seismic Design Categories, ICF wall houses are limited to two stories above grade. The maximum permitted house plan dimension is 60 feet, and framing clear spans are limited to 32 feet for floors and 40 feet for roofs (IRC Section R611.2). For houses in SDCs D1 and D2, IRC Section R301.2.2.2.1 limits the dead weight of concrete walls to 85 pounds per square foot for walls that are 6 inches of solid concrete. IRC Section R611.7.4 limits the minimum nominal thickness of the wall to 5-1/2 inches. Application of these criteria and the maximum unit weights in IRC Table R611.2 permits use of 5-1/2-inch flat ICF walls, 6- and 8-inch waffle-grid
walls, and 6-inch screen grid walls. The weight of interior and exterior wall finishes is limited to 8 psf (IRC Section R611.2). Floor and roof plus ceiling assembly weights also are limited by IRC Section R301.2.2.1 as for the other materials.

For houses in SDCs D1 and D2, IRC Section 611.2 limits the scope to rectangular houses with a maximum floor and roof aspect ratio (length to width ratio) of 2:1 and requires that the ICF walls be aligned vertically (stacked) without cantilevers or setbacks. An additional limitation is that the gable end portion of walls must be of light-frame rather than ICF construction. Further, the top of the ICF wall must be anchored to a required attic floor as described in IRC Section R611.9.

For houses in SDCs D1 and D2, IRC Section R301.2.2.2 requires engineered design for irregular portions of houses. The irregularities are discussed in detail in an earlier section of this guide. The exceptions to irregularities are mostly applicable to wood-frame construction and so do not apply. The 2003 IRC as printed refers to irregularities in IRC Sections R301.2.2.7 and R301.2.2.9, which do not exist; the intent was to reference IRC Section R301.2.2.2. IRC Section R611.8.3.1 repeats the prohibition of vertical offsets in floor framing (such as split levels) in SDCs D1 and D2.

IRC Section R301.2.2.4.4 triggers the requirements of IRC Sections R611 and R612 for all houses in SDCs D1 and D2. These requirements include all of the reinforcement and detailing provisions for concrete walls that provide the continuity and connectivity for the system to function effectively under wind or earthquake loads.

### 5.5.2 Wall Reinforcing and Anchorage

Reinforcing steel is of primary importance for concrete and masonry house performance. The reinforcing steel is what ties the components together and provides toughness to the concrete when it cracks. General requirements for reinforcing of ICF walls are provided in IRC Sections R611.3 through R611.5. Reinforcing is required for all ICF walls across all SDCs. IRC Section R611.7.1.2 imposes additional minimum reinforcing size and spacing limits for houses in SDCs D1 and D2. IRC Section R611.7.1.3 provides similar limits for horizontal reinforcing and includes requirements to provide for continuity of reinforcing around house corners and termination of horizontal reinforcement. Reinforcement is required to be dowelled into the foundation and extend for the full height of the ICF wall, including the parapet if applicable. Lap splicing of reinforcing is permitted.

Like light-frame wall bracing provisions, ICF wall provisions require a minimum length or percentage of the wall to be solid (without openings) so that the bracing wall strength is in proportion to the earthquake load. The minimum required lengths of bracing wall for ICF construction in each Seismic Design Category are defined in IRC Section R611.7.4. Minimum bracing lengths must be provided for wind load parallel and perpendicular to the ridge per IRC Tables 611.7(9A) through (10B). The required bracing length must be provided using wall segments not less than 2 feet in width. For all houses in SDCs D1 and D2, the bracing length requirements of IRC Table R611.7(11) also must be met using wall segments that are not less
than 4 feet in width. The increase from 2 to 4 feet provides a wall that is stronger and much better able to withstand cyclic earthquake loading.

Also of primary importance for house performance is the connection of the ICF walls to the floors and roofs, both for bracing loads parallel to the wall and out-of-plane loads perpendicular to the wall. The IRC addresses three types of connections to wood light-frame floors and roofs:

- Top bearing connections where the light-frame floor bears on the top of the ICF wall with light-frame walls above (IRC Section R611.8.1),
- Ledger-bearing connections where the floor or roof is supported off the face of the ICF wall by a wood ledger (IRC Section R611.8.2), and
- Top-bearing connections where the light-frame roof bears on top of the ICF wall (IRC Section R611.9).

It is important that a direct tension tie be provided from the wall to the floor or roof framing or blocking to resist loads perpendicular to the wall (this connection keeps the wall from pulling away from the floor or roof framing). This does not necessarily occur for lower Seismic Design Categories. For top bearing connections, sill plate to framing connections rely on minimum prescriptive fastening at framing perpendicular to the wall and no provision exists for a tension connection at framing parallel to the wall. For ledger-bearing connections, the direct tension ties shown in IRC Figures R611.8(2) through R611.8(5) are not required for lower SDCs, leaving the remaining ledger connection susceptible to cross-grain tension failure as illustrated in Figure 5-17. Very specific prescriptive anchorage requirements capable of resisting perpendicular-to-wall loads are given for sill or ledger to wood framing connections for houses in SDCs D₁ and D₂. Included are angle clips from sill to joist or blocking, continuous straps tying blocking together, and direct tension ties at ledger-bearing connections. Detailing is illustrated in IRC Figures R611.8(1) to 611.8(7) and R611.9. The specification of a maximum bolt size of 3/8-inch diameter for top-bearing connections is intended to favor bending of the bolt as a failure method over a brittle failure of the concrete or splitting of the wood. Larger bolt sizes should not be substituted.

Chapter 5, Walls

**IRC Section R611.8.3** addresses requirements for floor and roof systems. The floor and roof systems act as horizontal beams carrying wind and earthquake loads to the bracing walls. The increased weight of the ICF walls results in increased earthquake load in the floor and roof systems. For SDCs A through C, use of wood structural panel sheathing is required, and the **IRC** minimum fastening schedules of 6 inches around the perimeter of each sheet and 12 inches along intermediate supports are referenced. **IRC Section R611.8.3.1** triggers additional requirements for houses in SDCs D₁ and D₂. Minimum panel thicknesses are specified for floor and roof wood structural panel sheathing, minimum nail diameter and penetration are specified, all panel edges are required to be blocked, and the panel edge nailing is required to be 4 inches on center in SDC D₁ and 3 inches on center in SDC D₂.

**IRC Section R611.9.1** has similar requirements for roof construction but also contains two notable variations. First, the requirements apply to houses in SDCs D₁ and D₂. Second, where gable end wall conditions occur, it is required that a wood structural panel sheathed attic be provided to support the gable end wall (for truss roofs, the wood structural panel sheathing can be applied to the bottom of the truss between the truss chord and the ceiling finish material) and that the wall be anchored in accordance with requirements for anchorage to floor and roof diaphragms. **IRC Section R611.2** requires that the gable-end portion of this wall be light-framed. The writers of the ICF provisions preferred this solution over allowing increased ICF wall heights at the gable end due to the increased loads associated with concrete and the additional bracing requirements.

**IRC Section R403.1** requires that exterior walls be supported on continuous concrete or masonry footings and regulates minimum footing width and depth. If interior ICF walls are provided, these too should be supported on substantial continuous footings extended to a depth that provides competent bearing.

### 5.5.3 Problematic Gaps Between Prescriptive and Engineered Construction

The current **IRC** requirements for ICF wall construction reveal some gaps between prescriptive and engineered construction creating an opportunity for **above-code** measures to improve performance in areas of high earthquake risk.

There are no **IRC** maximum spacing limitations between lines of ICF bracing walls corresponding to the light-frame limits of 25 and 35 feet. In light-frame construction, these spacing limitations are intended to help distribute the bracing walls in proportion to the house mass (dead load) as well as to limit the loading to the floor and roof. This helps to reduce concerns regarding house rotation due to torsional irregularities and concerns regarding irregular floor and roof system shapes. For ICF wall houses, the scope limitation to rectangular houses reduces the likelihood of rotational behavior.

**Above-code Recommendation:** Careful balancing of bracing walls around the house perimeter is recommended to further limit torsional behavior. The maximum 60-foot house dimension will provide some limit for earthquake loads in the floor and roof. The cost of distributing the wall segments around the perimeter of the house should not result in any increased cost for construction.
For ICF wall houses, some of the irregularity limitations developed for light-frame houses have been made applicable. The concepts behind *IRC* Section 301.2.2.2.2, Irregularities 1 through 6, apply equally to an ICF wall house.

**Above-code Recommendation:** Any of the many required or recommended measures for areas of high earthquake risk would improve performance of ICF wall houses in areas of lower earthquake risk as well as in high-wind areas. Most of the recommendations would improve house performance in high-wind events. Priorities include wall anchorage using details developed to resist out-of-plane wall loads such as those shown in *IRC* Figures R611.8(2) to R611.8(7).

### 5.5.4 Quality Control

Quality control for ICF wall construction can play a major role in the satisfactory performance of the house. Important steps in ICF construction include:

- Reinforcing should be placed properly. Unless specifically designed otherwise, reinforcing should be located as near the centerline of the ICF cavity as possible but at least within the middle third of the wall.

- Anchor bolts should be secured into place before concrete placement (not placed into concrete following placement of the concrete) to prevent air pockets from forming around the bolt which reduces its strength.

- Concrete should be consolidated as it is placed into the forms to prevent voids from forming.
